In regard to his theory of the way in which the remedy acts, namely, that it destroys tubercular tissue without affecting any other structure, whether healthy or diseased, it must be said that he professes to have discovered a substance that has this extraordinary peculiarity—it is destructive to the cells concerned in the inflammation called tubercular. Possibly it may kill them directly because it is poisonous to cells engaged in the formation of tubercle, or it may kill them indirectly by producing inflammatory changes about them, or it may destroy them in some other manner. Whatever may be the way in which it acts, the statement is positive that it is an enemy of tubercular processes, not of tubercle bacilli. Indeed, the bacilli in the dead tissue may again infect the organism, and probably surgical interference will be needed to remove them. No substance is known that has an effect at all comparable to what is alleged for this remedy. Vaccination, of course, is by no means analogous in its action, since a living organism is introduced which does not destroy the small-pox poison, but only renders the body proof against it, and, moreover, does not, so far as we know, seek out particular cells or tissues for destruction.

We most earnestly hope that in this matter the medical profession will wait patiently and calmly for more facts. It is impossible to disregard or disbelieve Robert Koch, save after careful and prolonged investigation. So great is his name—so great his genius—that any observation of his carries with it a universally admitted probability of truth. In this matter, however, we can not see that he has adduced proof sufficient for his statements; we do not know what he has seen. In no disease is the patient's faith a more important element in the treatment than in pulmonary consumption, so far, at least, as temporary improvement is concerned. How often have we heard of a new "cure" under the use of which the cough, the expectoration, the fever, and the night-sweats were diminished and there was a gain of flesh! Yet the patients seem to have died, after all. What will be the future of Koch's discovery? We may hope much; we know nothing. In justice to Koch, it must be said that this seems to be precisely his own view, at least, so far as phthisis is concerned. In the mean time, it is not necessary for physicians to go to Berlin at present to learn about this remedy, even if they do not know how to give a subcutaneous injection. This they can learn at home, and they are not likely to learn anything else about the method abroad.

APPENDICITIS OR ECPHYADITIS?

The renewed interest recently aroused in diseases of the vermiform appendix has brought to light the dissatisfaction felt by some surgeons and pathologists at the use of the term *appendix* as a basis for the construction of words indicative of diseases of that organ or of operations made necessary by them. The reasons for this feeling are partly philological and partly economical—in the interest of economy of time and space. It is objected that *appendicitis* is a hybrid word, a Latin root with a Greek termination, a product that all lovers of order and uniformity in language are not inclined to employ; further, that it is wholly unsuitable for combination with the accepted termination signifying excision, *ectomy*, and, as removal of the appendix is an operation that has apparently "come to stay," we need something more convenient than that combination of four words to express it.

The same objections, and others, apply to *perityphlitis*. There is no *perityphlon*, consequently there is no inflammation of it, no perityphlitis; and *perityphlectomy* would be simply outrageous. What is the alternative? Liddell and Scott give us ἐκφύας and ἀποφύας as signifying an appendage, and Galen applied ἐκφύας particularly to the vermiform appendix. To this extent ἐκφύας may be said to have a title to be employed as the basis of the terms necessary to be employed to denote diseases of the appendix and operations incident to them, and its competitor is further handicapped by the use of *apophysis* to indicate a bony prominence. So, if we must have inflammation of the vermiform appendix, let us respect it as *ecphyaditis*, and let us find in *ecphyadectomy* the means of relief from the suppurative, perforative, and philological burdens it imposes.

MINOR PARAGRAPHS.

BRANCHIAL MALFORMATIONS.

Kostanecki and Mielecki, in a recent number of Virchow's *Arehiv*, give an exhaustive review of the literature and recorded cases of congenital branchial fistulæ, pharyngeal diverticula, and branchiogenic tumors and cysts. The anatomical importance of the relation of congenital cervical fistulæ to branchogenic malformations has, according to them, been clearly shown to be the result of arrested development of the branchial clefts. In the development of the embryo these clefts all close with the exception of the one forming the external auditory meatus, the tympanic cavity, and the Eustachian tube. Should any of the clefts remain open, a cervical fistula results, and it may be formed either from without or from within, and be complete or incomplete. The branchiogenic tumors and cysts found in this connection are epithelial in origin and dependent upon the branchial arches. The dermoids of the submental region and of the base of the tongue are not considered homologous with those of evolution or development, but they stand in relation to those which occur in the anterior mediastinum, and are the result of fusion of the entoderm with the ectoderm. The membranous and cartilaginous excrescences bear no morphological relation to the cervical fistulæ, but are independent products of the visceral arches, and the ear and ear muscles are heterotopic reproductions from the same parts. The congenital ear fistulæ stand in no relation to the first branchial cleft, but are disarrangements of the second. The cheek and lower-lip fistulæ are considered to be homologous with the cervical, which are secondary malformations in the first branchial arches. Hitherto, work on this question has been very much in the dark and problematical, but recent embryological investigations have given a pretty clear explanation of the causes of branchiogenic cervical fistulæ. The authors think that, if physicians would make an accurate anatomical history of congenital malformations coming under their notice, important scientific information would be elicited to clear up many doubtful points bearing on the question.

THE PHYSIOLOGY OF THE LARYNX.

Dr. Felix Semon, in a recent number of the *Proceedings of the Royal Society*, gives the result of considerable research and experiment as to the position of the vocal bands in quiet respiration in man, and as to the reflex tonus of the abductor muscles. While the laryngeal phenomena attending the act of respiration in man had attracted the attention of physiologists and laryngologists, yet investigation on this point had been comparatively limited, and nothing like unanimity of views had been obtained. The author, in order to show that the glottis was wider open during quiet respiration than after death or after division of the vagi or of the recurrent laryngeal nerves, had first drawn from corroborating evidence of trustworthy observers, and then from direct comparative measurements of the width of the glottis during quiet respiration and after death, and from the results of experiments on animals. Though the question would demand further elucidation, the outcome of his investigation was: (1) That the glottis in man was wider open during quiet respiration, inspiration, and expiration than after death or after division of the vagi or of the recurrent laryngeal nerves; (2) that this wider opening during life was the result of a permanent activity (tonus) of the abductors of the vocal bands and posterior crico-arytænoid muscles, which, therefore, belonged not merely to the class of accessory, but to that of regular, respiratory muscles; (3) that the activity of these muscles was due to tonic impulses which their ganglionic centers received from the neighboring respiratory center in the medulla oblongata, and that the regular activity of the abductors of the vocal bands during life belonged to the class of reflex processes; (4) that, in spite of their additional innervation, the abductors of the vocal bands were physiologically weaker than their antagonists; (5) that these antagonists, the adductors of the vocal bands, had primarily nothing at all to do with respiration, and ordinarily served the function of phonation only, their respiratory functions being limited to assistance in the protection of the lower air-passages against the entrance of foreign bodies and to assistance in the modified and casual forms of expiration known as coughing and laughing.

BUFFALO LITHIA WATER AS A SOLVENT FOR VESICAL CALCULUS.

The solvent influence of the Buffalo lithia water, from a spring in Virginia, over uric-acid gravel and calculus has been the subject of some recent communications to the journals. In the *Medical News* for November 8th two cases are reported by Dr. Samuel Hannon, of Washington, in which the lithia water afforded great relief by crumbling in pieces vesical calculi of considerable size. In one case, that of a woman, thirty-eight years of age, the water was used *ad libitum* for twelve weeks; in the other case, that of a man of sixty, it was used ten weeks, reducing the vesical concretions, apparently by dissolving them, and ameliorating the cystitis which was present in both cases at the time the use of the water was begun. In the second case, boric-acid washings of the bladder were at first used, and a doubt is expressed by the writer whether the crumbling process may not have been due, in part at least, to this agent as well as to the lithia water; at all events, the diminished irritation along the entire urinary tract was most marked and reacted favorably upon the patient's general health, so that the dyspepsia, insomnia, and diarrhœa—his former symptoms—began to disappear before the eighth week. In the first case, also, the reaction upon the general health was decided. Before the patient began to use the water she had suffered from attacks of renal colic for eighteen months, which were recurring with increased frequency; she had also had dyspeptic symptoms, hæmaturia, and one attack resembling uræmic convulsions. After three or four months the urine was found normal and the cystitis had vanished. Dr. C. H. Davis, of Meriden, Conn., has reported in the *New England Medical Monthly* a case of disintegrated calculus where the analysis showed that it was made up of uric acid with a trace of oxalate of calcium. The Buffalo lithia water was used in this case also. The vesical calculus in this instance was of two years' standing, and the patient was opposed to any operative procedure being undertaken for his relief. Within a few days after the use of the water was begun he commenced to get rid of portions of his calculus when urinating. For several days in succession he passed as much as a teaspoonful of detritus, and the passage of fragments was almost constant until, at the end of about a year, he was entirely relieved of all vesical trouble.

CARDIAC AFFECTIONS OF CHILDHOOD TREATED WITH STROPHANTHUS.

Dr. Moncorvo, of Rio Janeiro, has made somewhat extensive experiments with strophanthus in the cardiac affections of children. According to an abstract of his paper in the *Practitioner*, this drug is especially suitable as a cardiac and diuretic remedy in the diseases of childhood, because it is not only prompt to act, but completely harmless, even to children of a very tender age. Its action is both even and energetic. Fraser's alcoholic tincture has proved in his hands the preferable form of the drug, and when given in valvular lesions—both tricuspid and mitral—with diminished urinary secretion, promotes the return of tonicity of the heart, regulates the rhythm of its beats, and increases the amplitude and strength of the pulse. Its diuretic action is also well marked in a large proportion of these cases. It is a cardiac tonic in children's cases of pulmonary and broncho-pulmonary affections that are so frequently complicated with cardiac insufficiency. The happy results of the employment of this remedy often last long after its administration has been stopped. Numerous instances of the prolonged beneficial influence of the drug confirm the author in his opinion that strophanthus is pre-eminently the cardiac tonic for children.

PAMBUTANO, A SUBSTITUTE FOR QUININE.

Dujardin-Beaumetz has, according to the *Medical Press and Circular*, recently called attention to the antiperiodic properties of an extract obtained from the root of a shrub called pambutano. The aqueous decoction of the root has been largely and successfully used in the treatment of malarial fevers; it has been beneficial in a number of cases in which the symptoms did not yield to quinine. The isolation of an alkaloid has not hitherto been effected, but the plant contains various fatty bodies and essential oils in addition to a special kind of tannin. All the active properties of the root are extracted by maceration in alcohol at 60°. The writer in the *Press and Circular* adds that, while the high value of quinine as a febrifuge and antiperiodic is incontestable, the faults and failures of the old favorite do declare themselves from time to time, and hence the discovery of other vegetable products which have similar powers is not without importance, since some of these may and do succeed when quinine has proved ineffectual.

THE OPERATIVE TREATMENT OF MÉNIÈRE'S DISEASE.

Dr. Charles H. Burnett, in a paper read before the American Otological Society at its last meeting, gives an account of a

case of aural vertigo which he permanently cured by excision of the membrana and the malleus. Retraction of the chain of ossicles, induced by chronic catarrhal adhesion of the membrana and malleus to the inner wall of the drum cavity, was supposed to be the cause of the tinnitus and vertigo. Excision of these adherent parts of the conducting apparatus was performed under anæsthesia, with immediate relief, and there had been no return of the annoying symptoms, two years and a half having elapsed since the operation. This seems to be the first case reported as having been cured by operative methods. The result of treatment in this case suggests also that the origin of Ménière's disease is possibly often mechanical and not neuropathic.

THE JOHNS HOPKINS UNIVERSITY.

The advocates of the admission of women to the educational privileges at this institution have made favorable progress. At a recent meeting at Baltimore it was reported that the ladies moving in this matter proposed to continue their work upon the endowment fund until half a million dollars had been pledged to the Women's Medical School of the university. Among the active friends of the movement are Miss Mary Garrett, Miss Clara Barton, Mrs. Harrison, the President's wife, Cardinal Gibbons, Col. R. R. Porter, Dr. Richard H. Derby, Dr. H. D. Noyes, Dr. B. M. Murray, Gen. Felix Agnus, and Col. Rainey. Many of them were present at the recent meeting, above referred to, going to it from a distance in order to attest their hearty approval of the project.

GONORRHŒA IN THE FEMALE.

The *American Journal of the Medical Sciences* reports the work of Prochownick in the electrical treatment of recent gonorrhœa in the female, the result of which is published in the *Münchener medicinische Wochenschrift*. The author, in testing the antimycotic action of the positive pole of the galvanic current, has found that with this pole introduced into the uterus, and a current of 120 milliampères used for ten minutes, in every instance, after four séances the specific micro-organisms disappeared, and after six or seven applications the character of the discharge was entirely changed.

THE COOMBE LYING-IN HOSPITAL, DUBLIN.

It is contemplated to present the master of the hospital with a testimonial on the occasion of his approaching retirement from that office, which he has held for the last seven years. It is probable that an ex-assistant master (and Dr. Hoey's name is mentioned) will be appointed as his successor.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 18, 1890:

DISEASES.	Week ending Nov. 11.		Week ending Nov. 18.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus fever	0	0	0	0
Typhoid fever	25	9	21	9
Scarlet fever	74	9	59	7
Cerebro-spinal meningitis	2	2	2	2
Measles	174	15	161	13
Diphtheria	96	29	99	29
Small-pox	1	0	0	0
Varicella	2	0	3	0

The Orton Prize.—Dr. J. G. Orton, as president of the New York State Medical Association, has offered a prize of $100 for the best short popular essay on some subject connected with practical sanitation, under the following conditions: 1. Competition to be open to all. 2. Essays to be forwarded to the secretary of the association, Dr. E. D. Ferguson, Troy, N. Y., not later than August 1, 1891, accompanied by the name of the author under a separate seal. 3. Examination and award to be made by a committee appointed by the Council of the association. 4. The successful essay to be read at the next annual meeting of the association, and, if approved by the Council, to be offered for publication in the secular press, and issued in tract form or otherwise for general circulation. 5. Authors of essays, unsuccessful as far as the prize is concerned, but found worthy of special commendation, to receive intimation as to a proper disposition to be made of them.

An Assault on a Naval Surgeon in Brooklyn.—Dr. Delevan Bloodgood, medical director of the laboratory at the Brooklyn Navy Yard, was, on November 8th, the victim of a highwayman's assault. He was knocked senseless and robbed of all the valuables he had upon his person while returning at night to his residence near the Naval Hospital. The blow was probably given from behind by means of a sand-bag, and was only a little short of being murderous in its violence, but, fortunately, no bones were broken and no untoward symptoms have since arisen.

The Death of Dr. Richard J. Levis, of Philadelphia, the well-known surgeon and teacher, occurred on the 12th inst., at Kennett Square, Pa., after a brief illness. He was a native of Philadelphia, born sixty-three years ago, the son of a physician and coming from a family of French origin, but having an ante-Revolutionary history. The family name was De Levis, but the first American representative, who came over with William Penn in 1682, adopted the plainer way of writing it. The heads of the family have for two hundred years or more been practitioners of medicine or surgery, with a marked predilection for the latter. Dr. Richard J. Levis was an alumnus of the Jefferson Medical College, of the class of 1848. While pursuing his studies at that institution he was also an assiduous private student of Professor Mütter's, having in view the perfecting of himself in surgery as a specialty. In 1859 he was appointed surgeon to the Pennsylvania Hospital. During the war he was surgeon in charge of two military hospitals which were established near Philadelphia for the purpose of treating the deformities resulting from gunshot wounds, and while in these positions had nearly two thousand amputations under his care. He became surgeon to the Wills Hospital for diseases of the eye and lecturer in the same clinical department at the Jefferson school. In 1871 he was appointed to the surgical staff of the Philadelphia Hospital, and a few years later, when the Jefferson College Hospital was built, he was given a like position in it. He also became, about the same time, lecturer on clinical surgery at that college and at the Philadelphia Polyclinic and School for Graduates. From 1877 to 1887 he was president of the board of trustees of the Jefferson Medical College. He was also at one time the president of the State medical society, and in 1886 of the county society. He retired from practice in 1887 to his country home, called Cedarcroft, formerly the residence of the late Bayard Taylor. His fatal illness was pneumonia.

The Death of Dr. J. R. Quinan, of Baltimore.—We regret to record the death of Dr. Quinan, which occurred very suddenly on the 11th instant. Dr. Quinan was born in Lancaster County, Pennsylvania, but, after completing his medical studies in the Jefferson Medical College in 1844, removed to Calvert County, Maryland, where he remained, engaged actively in medical practice, until 1867. He then went to Baltimore, and resided there until his death. Dr. Quinan was well known throughout Maryland as a man of fine literary taste and ability, of considerable learning, and of enormous industry; and by the public at large he was particularly well known for his researches in historical subjects and especially in the medical history of his adopted State. To the smaller circle of his friends he was known as a man of singularly unselfish and generous character; thoroughly upright and honorable, alike in his ideas and in his actions, loyal to his convictions, a genial companion, a true friend; one who, himself modest to a fault, was

quick to appreciate the good points of another; one who, scorning everything base and mean as something alien to him, was yet full of charity and as far removed as possible from Pharisaical self-righteousness. Such men, though not filling the place in the world's estimation which is occupied by their more self-assertive colleagues, are still the true glory of the medical profession, and never more so than now, when the self-seeking struggle for prominence seems continually on the increase, and when the science of medicine itself, which is distinctively the science of benevolence and self-sacrifice, seems in danger of losing its character, while its votaries are being swept along in the universal rush for riches and preferment.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 9 to November 15, 1890:*

Alexander, Charles T., Lieutenant-Colonel and Surgeon, and Middleton, Johnson V. D., Major and Surgeon, are, by direction of the Secretary of War, appointed members of a board of officers, appointed to meet, at the call of the senior officer thereof, at the rooms of the Board of Engineers, Army Building, New York city, to examine such officers of the Corps of Engineers as may be ordered before it, with a view to determining their fitness for promotion, as contemplated by the act of Congress approved October 1, 1890. Par. 4, S. O. 261, A. G. O., Washington, D. C., November 7, 1890.

Cowdrey, Stevens G., Major and Surgeon. The leave of absence granted in S. O. 112, October 24, 1890, Department of Arizona, is, by direction of the Secretary of War, extended fifteen days. S. O. 263, Headquarters of the Army, A. G. O., Washington, November 10, 1890.

McElderry, Henry, Major and Surgeon. The extension of leave of absence on account of sickness granted in S. O. 214, September 12, 1890, from this office, is, by direction of the Secretary of War, further extended two months on surgeon's certificate of disability. Par. 28, S. O. 263, A. G. O., November 10, 1890.

Norris, Basil, Colonel and Surgeon, and Sternberg, George M., Major and Surgeon, are, by direction of the Secretary of War, appointed members of a board of officers, appointed to meet, at the call of the senior officer thereof, in San Francisco, Cal., to examine such officers of the Corps of Engineers as may be ordered before it, with a view of determining their fitness for promotion, as contemplated by the act of Congress approved October 1, 1890. Par. 5, S. O. 261, A. G. O., Washington, D. C., November 7, 1890.

Walker, Freeman V., First Lieutenant and Assistant Surgeon, Fort D. A. Russell, Wyoming. Leave of absence for one month, to take effect on or about the 15th inst., is granted. Par. 3, S. O. 85, Department of the Platte, November 11, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 15, 1890:*

Owens, Thomas, Surgeon. Ordered to the Museum of Hygiene at Washington, D. C.

Martin, H. M., Surgeon. Detached from the Receiving-ship Wabash and ordered before the Retiring Board.

Rixey, P. M., Surgeon. Continued in charge of Naval Dispensary at Washington, D. C., until November 20, 1891.

Green, E. H., Passed Assistant Surgeon. Promoted to Surgeon. November 10, 1890.

Smith, Howard, Surgeon. Placed on the Retired List. November 10, 1890.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending November 15, 1890:*

Carter, H. R., Passed Assistant Surgeon. Granted leave of absence for fifteen days. November 14, 1890.

Guiteras, G. M., Assistant Surgeon. Granted leave of absence for thirty days. October 29, 1890.

Hussey, S. H., Assistant Surgeon. To proceed to South Atlantic Quarantine Station for temporary duty. October 28, 1890.

Geddings, H. D., Assistant Surgeon. Granted leave of absence for fourteen days. November 14, 1890.

Groenevelt, J. F., Assistant Surgeon. To report to the Superintendent of Immigration for temporary duty. October 28, 1890.

Society Meetings for the Coming Week:

Monday, *November 24th:* Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, *November 25th:* New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society (private); Jenkins Medical Society, Yonkers, N. Y.; Boston Society of Medical Sciences (private).

Wednesday, *November 26th:* New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany; Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

Thursday, *November 27th:* New York Academy of Medicine (Section in Obstetrics and Gynæcology); New York Orthopædic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Friday, *November 28th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Letters to the Editor.

HERMAPHRODITISM.

151 Fairfield Ave., Bridgeport, Conn.,
October 29, 1890.

To the Editor of the New York Medical Journal:

Sir: The following case was brought to my notice by the commandant of police of San Salvador, Salvador, C. A., while I was in charge of the sanitary service of said Government. As it is a unique case, I should like to have it reported, with a view of ascertaining whether a similar case has ever been seen: J. H., a house servant of masculine features and movements, aged twenty-eight, height five feet seven inches, weight one hundred and thirty-nine pounds, was arrested by the police for violation of the law governing prostitution, which compels prostitutes to register with the Direction-General of Police and pass a weekly examination by a surgeon detailed for that purpose. On examination, both female and male organs of generation were found in a remarkably well-developed condition. The labia majora were of normal size, but flattened on their anterior surface. The labia minora and the hymen were absent. The vagina was spacious, four inches and a quarter long anteriorly and six inches posteriorly. The os uteri was torn on the left side. There was profuse leucorrhœa. Seven years before, she had given birth to a normal female infant. In place of the clitoris there was a penis which when in erection measured five inches and a quarter long by three inches and five eighths in circumference. The glans penis and the urethra were perfectly formed. The scrotum, which was two inches and an eighth long, contained two testicles about an inch in length and two inches and a half in circumference. The mons Veneris was sparsely covered with short, straight, black hair. Both sets of organs were perfect in their functions, semen being ejected

from the penis and the ovaries being capable of producing eggs. Scanty menstruation occurred every three weeks, and lasted but two days. Sexual gratification was said to be equally distributed between the two sets of organs.

Up to about seven years before, masculine clothes had been worn, but when pregnancy became apparent the local authorities compelled a change to female attire.

C. W. Fitch, M. D.

Special Articles.

THE OPENING RECEPTION IN THE ACADEMY OF MEDICINE'S NEW BUILDING.

The Academy's handsome and substantial new building in West Forty-third Street has been used for meetings for a number of weeks past, but has not until now been in the state of completion required for such an occasion as a formal opening. This took place on Thursday evening, the 20th inst. The reception committee, the names of whose members we have already published, had made arrangements for the comfort of a great number of guests, and the auditorium was occupied by the fellows of the Academy, by distinguished physicians from other cities, by a few non-medical men interested in such progress as the occasion exemplified, and by the ladies who accompanied them. The president, Dr. Alfred L. Loomis, occupied the chair.

The President's Address.—Dr. Loomis spoke as follows: Fellows of the New York Academy of Medicine, Ladies, and Gentlemen: I count myself most fortunate that it is my privilege to speak to you words of welcome in our new home. The only language which my heart prompts me to utter to-night is the language of congratulation—congratulations for the *past*, the present, and the future of our Academy. Forty-four years ago representative men in different departments of medicine, actuated by a spirit of devotion to a high scientific purpose, founded this Academy. Interwoven with its early history are the names of John Stearns and John W. Francis, Alexander H. Stephens and Alexander Hosack, John W. Draper and Joseph M. Smith, Valentine Mott and Francis Delafield, and a long list of others whose names and medical achievements made honorable the medical profession of their day. With such founders the membership of the Academy soon included most of the active medical workers in the city, and became the strongest and one of the most influential medical organizations in the State. From year to year it has grown in professional esteem and public confidence, and its advancing history has been stamped by the life and labors of such noble ones as Willard Parker, Alfred C. Post, James Anderson, Alonzo Clark, Edmond R. Peaslee, Austin Flint, William H. Van Buren, James R. Wood, Cornelius R. Agnew, and a host of less prominent, but noble, self-sacrificing spirits around whose memories we delight to linger.

Time will not permit me, at this hour, to even mention the many important papers that have been read and discussed, and the large amount of original work which has become a part of the scientific history of this Academy. As one reviews the scientific work of those earlier years, he congratulates himself that he is a fellow of such a fellowship. An organization which has given so much to the profession as ours has a *past* for each one of us to be proud of, and I may well congratulate you this evening on the past of the New York Academy of Medicine. We step, to-night, into a present full of promise.

In my inaugural address, less than two years ago, I stated that, in order that our Academy might become the center of the scientific activities of the entire profession of this city, it must have a suitable home, a building that should furnish accommodations for a large and well-selected library, with reading-rooms and commodious meeting-rooms for all our medical societies. Such a building is ours to-night, more elegant, more commodious, and better suited to our wants and work than the most sanguine could have hoped for two years ago. With a library capacity for 200,000 volumes, and a well-selected library of 50,000 volumes, supplemented by the largest and best collection of journals to be found in this country, we may rightfully maintain that we are in some degree meeting the highest requirements of scientific medicine. The influence which such a library will have, not only on the intellectual status and culture of the profession, but upon its moral tone, can not be estimated, for there is an atmosphere about a large and well-selected library which does not favor the growth of a mean, money-calculating spirit; it conduces to broadness, tolerance, and a love of the higher and nobler attributes of man.

Our membership has reached nearly seven hundred, and includes most of the active workers in our profession in this city and many in the State. Every specialty in medicine is represented by those who have become distinguished in their chosen lines of work. There are now established and well-organized sections in all the special departments of medicine and surgery, so that each fellow may find a place with congenial workers for making public the results of his own observations and experiments, under the sifting criticism of experts; and thus learn what may have been done by others in the way of support or in opposition to his own work. Not only are the combined scientific labors of our general meetings and sections, to a large degree, leading and guiding the medical thought and research of our own country, but their influence is being felt in the medical councils of Europe. We are also exerting an increasing influence on public thought and action. We are becoming a power in this city and State, which is being more and more felt in the legislative and economic work of our commonwealth. The public health and safety of our citizens are being more and more committed to our hands, with the conviction that by wise counsels and practical methods we shall protect it from the ravages of disease by an ever broadening and more perfect sanitary science. Our fellow-citizens, in response to our appeals made to them during the past two years, have shown by their sympathy and liberal donations that they are recognizing more and more the importance of our work and its influence upon the general weal. Let us act wisely, energetically, and unitedly, and we may be assured that in the near future we shall be able to turn more largely the influence of the accumulated wealth of this great metropolis into channels for the support and encouragement of scientific medicine. Our profession was never so full of promise as at present—never before were there so many strong men in its front ranks as now—never were there so many cultured and brilliant minds entering it as to-day. If this great and daily increasing power can be centralized, as is possible, within these walls, its influence on the social, domestic, business, and religious life of our city can not be estimated; already the better minds in all departments of science are turning to us for help and inspiration. There is no longer a strife of sects or creeds; but a struggle for the supremacy of intellectual power and broad culture over weakness and charlatanism. There is no place in the broad field of scientific medical inquiry for the would-be medical man who talks of the potential power of infinitesimal abstractions, and the so-called scholastic illusions. We are living in and are part of an age of facts, not fancies; work, not theories. This epoch

in medicine is indeed more brilliant and eventful than any which has preceded it, and the prospect grows constantly more encouraging and richer in possibilities. The efforts of the many enthusiastic workers who to-day are struggling for truth in medicine must produce a general advance, notwithstanding, as Dr. John W. Draper once said: "There has been through all the ages, constantly hovering about honest workers in our science, a host of impostors and quacks, who will continue to thrive so long as there are weak-minded and shallow men to be deluded, and vain and silly women to believe."

I congratulate you, then, that with the most advanced workers in every department of scientific medicine gathered in our fellowship we meet to-night about our own hearth-stone in full possession of all those facilities which were needed to render our work most efficient and stimulate us to still higher achievement in the future, so that the work done in these halls shall have a forming and crystallizing power on the medical literature of our whole country. The days of doubt and anxiety are past, success has ceased to be a question, the auspicious present marks the beginning of a new and broader career for our Academy. It is here in the center of this great city to do its part in stimulating its intellectual and moral forces. With increasing opportunities come deeper obligations. Our future must not be gauged by past successes or present advances.

We are under obligations to the past, but under bonds to the future; as we in turn pass this trust to our successors, to those who in the future are to be the exponents of the lofty mission to which this building is dedicated this evening, it must not have suffered in our hands, but have grown and broadened under the impulse of true enthusiasm and faithful work. Yesterday we read the history of the past, to-day we make a history for the future, and. whether he will or no, every fellow in our number must leave his mark, be it little or much, in the records of this Academy. Let us be inspired, then, with the thought that our fellowship shall become a power in raising our profession to the high place which the future shall assign to it, centralizing its influence and elevating it socially and intellectually to a position which was not hoped for in the past or attained to in the present.

Our future must be and will be interwoven with the many and rapid transformations that are to take place in every department of science, and our relations must become more and more intimate with the great public, who are fast realizing that the first mission of our labors is the prevention of disease. The career of the physician of the future will be nobler and pleasanter, because he will have less of ignorance and prejudice to combat, but he will require a higher culture than his representative of to-day. Here in this library and in these halls both the medical profession and the philanthropist will find that inspiration which shall give birth to a greater devotion to the alleviation of human suffering and a better realization of our duty in the elevation of the masses to a higher civilization. We must never look backward, but always forward. Provided with the machinery of wisdom we have inherited, but not wise in our own conceit, let us make this building the great workshop where the fires of scientific enthusiasm and persistent labor shall smelt from out the ores of our daily experience the pure metal of truth that, cast in the molds of patient thought and polished by the sharp emery of keen and kindly criticism, may some day furnish to generations yet unborn armor and weapons with which they will advance victorious over all the forces of death save threescore years and ten.

So shall the congratulations which we utter to-night re-echo from these walls when other voices recall this day. Join with me, then, in thanksgiving to the Great Physician for what has been accomplished, and in this invocation: that these walls may not crumble or cease to shelter faithful, earnest, Christian men until suffering humanity is free from its bondage to lust and excess, and is victorious in its struggle against the invisible arrows of disease.

The Anniversary Oration was then delivered by Dr. Edward L. Keyes, who said:

Mr. President, Fellows of the Academy, Gentlemen, and Ladies: If there are sermons in stone, then an address has already been delivered to you to-night on entering these walls, in a strain of greater dignity than any to which I may aspire. The fact of the existence of this building at all in the graceful form in which you see it, devoted as it is to be to philanthropic and humanitarian ends—this in itself is a whole volume, a canticle of praise to the energy of its promoters, and a pæan of gratitude to the liberality of those whose material bounty has made its erection a possibility. Those of us who are to possess this well-equipped arena for scientific effort, this nucleus from which shall radiate ever-broadening lines of medical thought, have lived to see a good day, and to enter the promised land toward which our earnest expectancy has led us through many a long hour and weary year; and in contemplation of the work accomplished, in that grateful lassitude which accompanies the consummation of a successful effort, we might perhaps with better grace muffle our ineffective voices and allow the stones to discourse to you in the eloquence of their majestic silence. Yet this may not be. Some articulate words are called for, and if I, who have been honored by being made the mouth-piece of my fellow academicians, can, as an impersonality, render to you for them any words in harmony with the occasion, the accomplishment of the pleasant duty will be its fitting reward.

An academy is an institution sanctioned by illustrious precedent in that group of devoted followers who, in the groves of the suburb of Athens bearing this name in the year 348 before Christ, clustered around Plato as he "taught the truth"; and to teach the truth after investigation has been the proper function of the academy ever since that day. The various institutions of learning which in different scientific fields have borne this name have made for themselves everlasting renown and have established a criterion by which, if our little body of earnest workers is to be judged, it behooves us to spare no effort that our results may be deemed worthy to be enrolled upon the same scroll of honor.

The age in which we live is distinguished notably along three prominent lines—by material progress, by the broad dispensation of rational charity, and by the far reaching effectiveness of scientific study in its practical application to the needs of mankind. This building in which we are assembled represents a crystallization of the essence of all these lines. The material progress is represented by the graceful outlines of the building and its commodious internal structure, which the architect has ably conceived and the workmen have faithfully executed. The very existence of the building is the acme of a broad charity, since it stands for the accumulation of many hard-earned dollars, that this institution may live and become effective, not solely for those who make immediate use of it, but that the fruit of their labors may spread abroad through the land for the benefit alike of all who are in need; and it stands for science, for it is the rostrum from which science speaks; it is the arena in which science contends; it is the soil in which are implanted the roots of that tree of medical knowledge in the branches of which the investigator may find the bud, the flower, the ripening fruit of past experience; it is the fountain from which shall emanate rivers of refreshing sweetness to cool and succor the parched sufferer along the dusty highways of disease.

And what to say of the academic body itself, of which this edifice is the outward and visible sign? Conceived, as its historians have often narrated, conceived in the spirit of good fellowship and brotherly kindness, on the evening of November 18, 1846, at a dinner of the Society for the Relief of Widows and Orphans of Medical Men, it took shape December 12, 1846, with the sanction of about two hundred and sixty physicians, under the immediate direction of Alexander H. Stephens, assisted by Parker, Watson, Mott, Isaak Wood, Smith, and others, was born on the 6th of January, 1847, and baptized by legislative enactment of incorporation on the 23d of June, 1851.

The motive for its formation was stated by its founders to be a "lack of harmony and concentration of effort for scientific purposes in the profession" and a desire to elevate a barrier against quackery, which, at that time, it appears, had reared a more formidable front than before or, possibly, since that day. At its birth its future functions were defined to be: 1. The cultivation of the science of medicine. 2. The advancement of the character and honor of the profession. 3. The elevation of the standard of medical education. 4. The promotion of the public health.

The Academy is, therefore, now in its fifth decade. It has lived through its babyhood and period of riotous youth, homeless at first, and wandering about seeking shelter, and having no roof to call its own, until well along in its twenty-seventh year, when, on December 24, 1874, it secured, largely through the energy of Dr. S. S. Purple, a permanent abiding place at No. 12 West Thirty-first Street.

There might almost be said of the Academy what has been tersely written of the life of man, dividing it into decades:

At 10, a child;
At 20, wild;
At 30, sound, if ever;
At 40, wise;
At 50, rich;
At 60, good, or never—

except that the Academy has been from the beginning good, a quality which may not be affirmed with equal confidence of all men. For surely at ten the Academy was a child and a wanderer in the streets; at twenty we may be pardoned for declining to inquire into her follies; at thirty she was certainly sound—indeed, there never has been a question of the health of the organization; at forty who shall deny that she was wise, for it was in the early forties that the necessity for expansion was felt, and that spirit generated which has culminated in this our forty-fourth year in the completion of this modern home, in which the treasures of our library will be adequately protected from fire, and wherein ample provision has been made for the convenience of present work and future expansion. And in signaling this triumph of the Academy's fourth decade, it is impossible not to pause and pay tribute to our president, Dr. Loomis, whose energy, zeal, and ability have contributed so largely toward the accomplishment of the result.

It is hardly necessary to carry the simile further. At fifty the Academy can not fail to be rich. She is rich now in the love of her children, in the respect in which she is held by the community at large; she is rich in her library and in the accumulation of good work by her members. This is the material wealth of a scientific body, and of this she has already a fund and a steadily increasing store.

At sixty the Academy becomes immortal, and will remain, until the consummation of Time, a pillar of beauty and strength, an integral part in the grand temple of Science which is being reared by zealous and loving hands throughout the length and breadth of the entire earth.

And how has the Academy fulfilled the aspirations of her founders? Surely the end is not yet, and more remains to do; but in the four directions which were defined at her origin as her special lines of effort, her advance has certainly been satisfactory. The science of medicine has been cultivated; the division of labor into section work has brought together spirits scientifically akin, and the quality of the material presented to and digested by these sections is of a high order and of steadily increasing excellence.

The character and honor of the profession have been sustained; struggling factions have been dominated by wise counsels, and threatened rupture averted by the exhibition of a broad spirit of professional charity, which has helped to steady and elevate the quality of the professional gentleman without as well as within the academic circle.

The weight of the Academy has always been thrown into the scale to help to raise the standard of medical education, both by the personal effort of the fellows, many of whom have occupied high positions as instructors in the various institutions of learning, and in efforts to help shape legislation toward the accomplishment of the same result upon a larger scale.

That the promotion of the public health has been an object of academic solicitude is witnessed by the present existence of our efficient city Board of Health, which was conceived and formed in the bosom of this Academy in the interest of the citizens of New York.

The workers in the academic field have not been very numerous. The present roll, the largest ever possessed, numbers seven hundred; but in that number may be found the names of nearly every living physician of recognized eminence in the city and immediate neighborhood, and it is difficult to mention any of the illustrious dead of our profession whose names will not be found written upon the roll of the Academy, as well as imprinted upon the memory and in the hearts of those who loved them for their kindliness during life. How shall I mention any without slighting more—Francis, Mott, Stephens, Parker, with his genial smile; Watson, Post, Peaslee, Flint, the good physician, the crystallization of benevolence; Rogers, Bumstead, Buck, Wood, the man of action; Delafield, Clark, Dalton, Anderson, Agnew, the Christian gentleman; Hamilton, Sims, Van Buren, the man of judgment, the man of dignity, a very man, a prince among his peers—but why prolong the list? The good men have been ours, the good men are ours, and their work, the best of it, is fostered by this Academy and turned to good account.

And yet the high success of the few is not the measure of the usefulness of the Academy. These illustrious ones would have glittered without the Academy. Their luster is shed back and illumines the whole body in which they mingled, and multiplies there for the good of the community at large.

We in our scientific struggle and effort are much like children. The vastness of the field belittles our personality. The pretentious few who arrogate to themselves a personal superiority are more than liable to be left behind by the patient seeker after truth, whose path is lightened by the glowing rays of human kindness. Children we are indeed!

"We go forth like children in the morning,
Scattering to spend the summer hours;
One his brow with laurel wreaths adorning,
One to saunter 'mid a grove of flowers,

"One to lose his way and wander, straying,
Till the twilight, frighted and alone,
One, it may be, wearied with his playing,
Wending home his footsteps ere the noon.

"But whatever fate to us is given,
All, when day is done, again shall meet,
And at nightfall, 'neath the stars of heaven,
Shall be gathered at our Father's feet."

To obtain an idea of the relative standing of this Academy we must compare it with other analogous institutions. The Imperial Academy of Science in Vienna and that of France are scientific, not medical, bodies. There is a Royal Academy of Medicine in Belgium, one in Italy, one in Ireland; there is an American Academy of Medicine, one in Kansas, and one in Detroit, but the moderate scope and importance of these various academies relieves them from comparison. Germany is justly proud of her two distinguished associations in Berlin—the Medical Society, under the presidency of Virchow, and the Society for Internal Medicine, under the leadership of Leyden. Illustrious names glitter in each of these constellations, but neither has a building of its own yet, although the Medical Society is now erecting one in company with the Berlin Surgical Society. The library of the Medical Society is of about two thirds the size of our library, while that of the Society for Internal Medicine is insignificant. The great Austrian medical body, the Royal Imperial Society of Physicians in Vienna, justly renowned for the brilliancy of its work and the standing of its members, has no building of its own, and a library of something over eleven thousand volumes—not one third the size of ours, although the society is ten years older. Of the Surgical Society of Paris and other foreign medical associations it may be said that, whatever their distinction, they are not sufficiently analogous bodies to be fairly compared with our Academy.

Two foreign institutions, however, fulfill the conditions: The Academy of Medicine in Paris, and the Royal Medical and Chirurgical Society of London, upon the general plan of which our organization was outlined. As between these two and ourselves at this date, in evidences of material prosperity at least, our Academy holds its own. As to the scientific standing of its members, I shall not draw comparisons. It is enough to say that each of them contains the flower of the medical science and art in the districts in which they are respectively situated. In this country there is no other academy (except the relatively unimportant ones I have mentioned), although there are many notable medical and surgical societies; but the extent of our land and the widespread distribution of its talent make it probable that others will shortly arise.

Comparing, then, some of the main points in the three that I have selected, I may say that each has a building of its own, that of the French Academy being a temporary one. They have the funds and propose constructing a suitable home in the near future.

The Royal Medical and Chirurgical Society, London, founded in 1805, has a membership of 700; the seating-capacity of its largest hall is 300, the area of the hall being 40 by 50 feet, and the foundation area of the building 50 by 200 feet.

The Academy of Medicine, Paris, founded in 1820, has a membership of 110; the seating-capacity of its largest hall is 92, the area of the hall being small, and the foundation area of the building small.

The Academy of Medicine, New York, founded in 1847, has a membership of 700; the seating-capacity of its largest hall is 350, plus extra opened-up space 250 = 600, the area of the hall being 42 by 57 feet, and two extra smaller rooms that may be opened into it; the foundation area is 75 by 100 feet.

All have libraries, but on this point we may seek a wider field for comparison. Our library, which is, I believe, the youngest on the list, and which always gratefully recalls the names of its chief munificent donors—Purple, Dubois, Bumstead, Stone, Jacobi, and many others whom time forbids me to detail—was founded by donations in 1877, and never bought a book until 1879, eleven years ago; yet now, safely housed in a fire-proof home, we are proud in possessing the third place numerically among the medical libraries of America, and the fourth place, as far as I can learn, among the purely medical libraries of the world. In this country the library of the Surgeon-General's Office in Washington, founded in 1865, is the largest; that of the College of Physicians in Philadelphia, more than one hundred years old, the second.

Comparative Table of Medical Libraries.

	Date.	Volumes.	Journals.	Current Journals.	Pamphlets.
Academy of Medicine, Paris.....	1820	130,000	18,000	390	
Surgeon-Gen.'s Office, Washington.	1865	97,886	33 173	Over 700	144,887
College of Physicians, Philadelphia	1789	45,000	.....	400	
Academy of Medicine, N. Y.....	1847	40,000	.....	400	
Medical and Chirurgical Society, London.....	1805	36,000	.....	150	
Medical Society, Berlin..... ..	1839	About 30,000			
Royal College of Surgeons, Dublin.	....	About 25,000			
Medical Library Assoc., Boston ...	....	19,365	.....	381	19,100
New York Hospital Library, N. Y.	....	18,386	.....	109	No record kept
Royal Imperial Society of Physicians, Vienna	....	11,669	.....	132	
Aberdeen Medical Society, Scotland	....	6,000			

So stands our Academy, and such she is when compared with other analogous institutions in other parts of the world. Considering her age, she need not be ashamed. To fulfill her destiny and consummate her function requires only a continuance of the zeal which has attended her development from the first and a common impulse among her members to work for work's sake.

Here in this hall, now radiant with gracious smiles of approving friends, must be fought out many a desperate scientific battle. Clad in the armor of scientific method and wielding the sword of personal experiment and investigation, contending individuals and contending factions shall battle for the supremacy of their ideas until these walls shall resound with the din of conflict; and from the blows given and taken with such weapons upon such honest armor there shall scintillate and radiate sparks and flashes of truth, living fire, to be added to and heaped upon the burning flame that glows forever upon that common altar of science at which we all worship, a flame to act as a beacon of safety upon the hill-top to encourage those for whom the battle is fought—the patient, suffering victims of disease—and a flame which, within this academic body, shall serve as a cloud of smoke by day and a pillar of fire by night to guide and guard the honest investigator in his never-ending endeavor to teach the truth.

The Library.—Dr. A. Jacobi spoke as follows:

Mr. President, Ladies, and Gentlemen: A circular published by a special committee of this Academy in January, 1888, contained the statement that the New York Academy of Medicine was an incorporated institution then more than forty years old; that its object was the cultivation of medical science and art; that this aim was, among other means, reached by maintaining reading-rooms which furnished nearly all the medical journals of the world, and by collecting a library which was—and is to-day—free to the fellows of the Academy, to the whole medical profession indiscriminately, and to the public at large. Our library was steadily increasing, the capacity of its shelves was strained to the utmost, the building was not fire-proof, and our accumulated treasures were in constant danger. For these reasons we appealed to both the profession and the public for aid in procuring for our meetings and our books a fire-proof building large enough to accommodate two hundred and fifty thousand volumes, spacious enough to afford quarters to all the

scientific societies of the city, stately enough to worthily represent the medical profession of the metropolis, and able to testify both the unity and earnestness of that profession and the sympathy of the city, which at the same time is the largest in size and the greatest in commercial power of the continent.

This library of the Academy of Medicine had a slow but steady growth. Thirty-three years ago, when I was admitted to membership, in the presence of the great and good men who then were the guiding stars of the profession—Alexander H. Stephens, Valentine Mott, Horace Green, Gurdon Buck, Edmond R. Peaslee, Edward Delafield, John Francis, John Watson, Ernst Krackowizer—there was no library at all, not even a medical reading-room in the city. It took many years before the Journal Association was organized, which furnished, in a room fitted up for the purpose at No. 64 Madison Avenue, the current medical journals. Other years elapsed until an amalgamation of the Journal Association and the Academy of Medicine, then at No. 12 West Thirty-first Street, was brought about. The accumulation of the annual volumes and a valuable collection of American journals and other books presented by two fellows were the first stock of the library. The journals were paid for by an appropriation of the Academy, which, being small in the beginning, for many years amounted to from three to four thousand dollars annually. More could not be spared. Thus it was that we could not purchase new books. Occasionally a sum was raised by voluntary contributions for the purpose of buying the collection of a deceased member, certain publishers would present us with their publications, authors donate copies of their writings, fellows and others give old and new books, and men interested in special branches of literature furnish a shelfful of special works. That was our library. Thus it grew slowly but steadily. In the course of years our stock of journals became more and more valuable, but what we wanted was a regular supply of new books, for which we had no funds.

On the 2d of October, 1889, when I had the honor of addressing you at the laying of the corner-stone of this edifice, I could refer to the fact that at last we had, for the purchase of new books, a special library fund of ten thousand dollars, half of which was a memorial gift. For the same purpose and in the same spirit the widow of a deceased fellow and vice-president has since presented another special fund of ten thousand dollars, so that one fifth of the sum required for the perpetual endowment of the library is now secured. We are thus approaching the time when New York city will possess a medical library fully adapted to meet its ends. What are they? A large library, besides being the proof of existing culture and accumulated intellectual labor, fulfills its destiny by giving information. Here the medical man with scanty means will find his text-books and monographs to aid him in unraveling the obscurities of a difficult case on hand. He with an ample library of his own will come here to consult rare books, old journals, expensive works. Here all the journals of the world may be consulted from day to day; here those who are engaged in literary pursuits find their historical records. But what a library is most successful in is the inculcation to a great many of the habits of study and research. In that result the public is very much interested. Its safety and dignity require cultured and erudite physicians.

In the same degree that the ethical and intellectual standard of society is raised the community will demand a higher standard of education and culture on the part of its liberal professions, among them the medical. A profession is called liberal in this, that it is generous, charitable, and high-minded; in this, that it liberates its members from ignorance and mental and moral hebetude. But in reality the medical profession of the country has been mostly liberal in this, that it has admitted to its ranks uneducated persons of all colors, sexes, ages, and previous conditions of servitude and illiteracy. Instead of being a truly liberal profession, it has merely been too liberal. In this tendency it has been encouraged, or rather this inferior standard has been forced upon the medical profession, by the public. He who requires manners in his corn cutter, and demands gentleness in his tailor, would often not object to selecting for his family physician and public hygienist a medical adviser with the orthography of a village school, the touch of the corner grocer, and the mental level of a soap-peddler.

From this depth the profession has risen spontaneously by study and its indigenous moral development. Not all of you know, however, to what extent you are under obligation to the medical profession. Fifteen years of incessant agitation were required to finally pass the bill for the establishment of a State Board of Medical Examiners. If in future you are protected against practitioners who have nothing to show besides their diploma granted by a college—no matter of how high or low standing—if the license to practice on you, your parents, and children is made dependent on a second examination, you owe that blessing to the exertions of the medical profession. You might have made the result more striking. If the public had understood its interest you would have worked with us, in behalf of making the State board one, and not three.

Another achievement of the profession which concerns you as much as it does us is the final passing of the bill requiring some degree of general education on the part of every medical student who expects to obtain his medical diploma. Thus a step is made in the direction of rendering the profession more liberal, more cultured, more effective, more fit to take charge of the most sacred offices that can fall to the lot of men. For the holiest and greatest of the objects of human study and care is man. That is so much a part of the creed of the medical profession that you can imagine our painful and contemptuous surprise on learning that a medical man in a public position, but fortunately not one of us, worked all winter to have the law repealed. Fortunately not one of us. For from its very first days this Academy of Medicine has had the elevation of the standard of medical education and culture inscribed on its banner. That object has become such a settled axiom in the mind of every fellow that years ago it was no longer considered necessary to retain it in just as many words among the written laws.

In this tendency you can sustain the efforts of the profession. Insist upon this, that your physician be a gentleman and a scientist, and do something for that purpose yourself; for the State does not contribute to that end. The State is only society organized for certain purposes of co-operation and protection. But medical education, though ever so indispensable for the pursuit of health and happiness and the training of erudite and liberal physicians, has not been recognized among them. But you who do not say to the hungry, the cold, and the naked, "Be ye fed, be ye warmed, be ye clothed," without helping them to food, fire, or clothing, must not expect a profession that always works in the private and public interest of yourself and all those dear to you and yours to be at once learned, erudite, and wise, and refuse aid in its efforts to perfect itself and benefit the commonwealth—aid by pecuniary support, by your social influence, and also by some occasional gentle political pressure on our representatives in Albany.

Our greatest drawback has long been that we had no large class of learned medical men, such as study for study's sake, irrespective of pecuniary gain. Our profession has always consisted of practitioners. The necessities of life have acted upon the medical fraternity as on the community at large, which knew but exceptionally of art, of music, of philosophical refinement so long as the country was still wrestling with the diffi-

culties of the soil, the insufficiency of commerce, and the hampering of poverty. Thus the immense majority of the medical men of the country gloried in being practical, and that only. That there were architects who never laid a brick, mathematicians who never triangulated a mountain, astronomers who never sailed a ship; that no cathedral, no coast survey, no ocean travel could exist without them, that indeed there was no rational practice without an underlying theory, was not considered. The very strongholds of medicine, histology, physiology, the fields of experimental labor and microscopical research, all those branches which you can not immediately exchange for cash, have been neglected among us until lately. Like special laboratories, it is but a short time since great medical libraries have sprung up in Washington, Philadelphia, Boston, and New York. The sooner we admit that we have been far behind Europe in that respect, the better for our scientific future. Indeed, the intellectual maturity of a nation can best be measured by the amount of its original and unpaid research. Europe knows that thoroughly. The intellectual atmosphere of Paris depends greatly on its university. The universities of Germany, with their independent workers and thinkers, have always been the pride of the nation, even in the distress of national poverty and political humiliation. In all of them the principal means of information, through centuries, have been their large libraries. And it will be our library round which the scientific interests of the profession will largely center; but not of the profession only, for the Academy, as it opens its doors to whosoever will attend, without regard to membership, has always held that in order to increase the number of its beneficiaries, it must make its library free. This is so well understood and so highly appreciated that the city has remitted the taxes on its building. A medical library contains of necessity many works and journals of interest to professional men besides medical. The lawyer and physician have many studies in common. There are in the city two societies for the special study of forensic medicine and medical jurisprudence, both of which can be better studied in a medical than in a legal collection. Nor is a medical library such as we have, and mean to increase, a forbidden fruit to the intelligent, well-informed non-professional man or woman. Fortunately, there are a great many good popular works, besides those compiled for an ephemeral market, which treat of physiology, hygiene, statistics, and other topics of universal interest.

Therefore we hold that the profession has a right to look to the public for appreciation and aid. We are not situated as they are in Europe, where educational institutes, as they are controlled, are also supported by the Government, for the democratic spirit of our social and political institutions is opposed to centralization of that kind, and the generosity of the citizens has often been appealed to and hardly ever in vain. There was a time when the Church, centralizing all information, beneficence, and social and political influence, was the only legatee of the rich and benevolent. Now there are a hundred opportunities for liberal outlay. To select the proper ones is an art. I suppose it is a great achievement, which only a few select ones can attain, to make money; but it is a greater art to spend it both generously and profitably in the interest of science and charity. The greatest of all charities, however, is to benefit mankind by leveling the road of science. It is not millions we want. A hundred thousand dollars will clear this temple of science from debt and swell our library fund to a sufficient sum, the interest of which will forever supply us with everything medical and scientific that will appear in any country. Well-to-do ladies and gentlemen will, I hope, not leave this building without making up their minds to contribute their share to the extinction of a debt which the community owes to the profession and to itself, through improved educational facilities. "Let your light so shine before men that they may see your good works."

In conclusion, my friends of the profession may permit an additional word or two on the subject of the library, which is so dear to all of us that it was selected as the subject of a special address to-night. In one of its retired nooks I was sitting a few days ago, contemplating its past and future. I sat wondering how long it would take, and whether any of us older men would see the day, until America, after having given the political world the guiding example of a stationary popular government both conservative and perfectible, led the world of science as it was leading that of politics and, we hope, of healthful social development; wondering also how much this head center of the medical profession and this ever-growing library would contribute to that consummation, which you can hasten by industrious, honorable, and modest work, but by work only.

This library of yours started from small beginnings, like medicine itself. It comprises the labors of thousands of workers assiduously employed through long centuries. That there is one of them that would not be missed is difficult to say, for the co-operation of the many, the gradual development of ideas, the slow changes in experience and doctrines, are of as much importance as the revolutionary and epoch-making labors of the greatest; for no single man stands alone, a law to himself and others. Even genius is the child of its time. No Washington or Lincoln, no Hippocrates or Aristotle, no Virchow or Pasteur, or even Koch—none of these immortal ones is a world by himself and an isolated self-lit sun illuminating and warming the universe. Every one has been raised on the shoulders of his predecessors. By that knowledge it is that, while hope and energy are aroused, patience is taught to the individual and the profession, for, while life is short, science and art are unlimited and eternal; and the comparison of what you furnish yourself with the existing mass of accumulated knowledge inculcates modesty and enhances zealousness. Thus good citizens are made and model scientists. Besides, what to the pupil is the information gathered from the lips of his master, that is for you the collective bequests of all centuries as represented in your library. Thus an intellectual kinship is formed between you the living and the spirit of all eras of history. That is what the study of the history of medicine teaches us, which we have so long neglected.

Pondering over the shelves, you behold abstract scientific treatises, works on practical therapeutics, and books on art and appliances—all of them composing our beloved "medicine." Remove the theoretical works on anatomy, histology and embryology, experimental physiology, physics, and chemistry—what remains? The wreck of the edifice, the foundation of which is torn away.

Look at the shelves holding special literature. There the specialist will comprehend that his doctrine and art are but a minimal trifle when compared with the surrounding wealth, and that the basis and link of all specialties is general medicine. Every one of them was evolved from a minute bud of the great tree, and but few have ever been able to grow up with anything like independence. Thus medical science and art is shown to be an organism of slow, consistent, historical growth. Even the very excrescences—call them fallacies, superstitions, theories, schools, or sects—do not disturb the organic economy. In accordance with this, your very library, the representative and exponent of all medicine, is no longer a mere collection, but a vitalized organism.

That is why there is an atmosphere of solemnity in your large library, for you are standing in the presence of the spirit

and soul of all previous ages, each evolving from and connected with its neighbor. That is why a library is to the scientist what the church to the pious, or a museum of a hundred gems like that which a generous fellow presented to our reception-room, to the artist. No consideration of lucre invites you there. While nourishing your minds, you disconnect yourself from the embarrassments of trivial employment and deliver yourselves from the merely terrestrial. In that way the idealism is nurtured that no feeling and thinking man is to be without; idealism, without which no nation can expect to live. When she lost it, even Hellas perished, though she had given birth to Solon, Pericles, Aristides, and Sophocles.

Let me suggest this reflection as a platform, my young colleagues. It is not a dream, but a reality, if you will make it so. By so doing, not only will you elevate your august science and the noblest of all callings, but you will also remain in constant and indissoluble intellectual and moral contact with the most cultured elements of society. If you do, this evening, which is both an anniversary and an inauguration, will prove a blessing for all future time to both the profession and the community. Look upon this edifice not merely as a new and commodious building, but as the visible portal into a new epoch. If you do, you will consecrate this solemn occasion as the Fourth of July of American Medicine.

Remarks by Dr. John S. Billings, of the Army.—Dr. Billings said: I beg to offer very hearty and sincere congratulations to you on this occasion of your formal taking possession of a comfortable and satisfactory home of your own, which I hope will be the beginning of a new era of prosperity and usefulness. And I offer these congratulations and good wishes, not only as an individual warmly interested in the welfare and work of the Academy, but also in behalf of the Medical Department of the Army, very many of whose members have enjoyed your aid and hospitality while on duty in this vicinity.

There are many features about this medical home upon which I might comment, but to me the central and most important feature is its library and reading-rooms. In this assembly hall you may sometimes meet and receive instruction from many of the famous living physicians of New York, but in the library you may at all times consult with the wise and illustrious of our profession of all times and countries, living and dead, upon whatever subject most interests you. You can always find good company there; they are never in a hurry, never obtrusive, and, while they can not always tell you what you want to know, they can usually tell you something new that you ought to know, provided you question them aright.

Perhaps a very few words about library matters, based on my experience in your Washington branch, the Library of the Surgeon-General's Office, will fatigue you as little as anything else I could say. The kind of literature most needed in a library of this kind is medical journals and transactions, and next to these come statistical reports relating to diseases and deaths in different countries, States, cities, and institutions. The reason for this is that no physician would find it worth while to obtain and preserve in his own library one twentieth part of the periodical and medico-statistical literature which is now in course of publication, and yet it is the papers and figures in these which he most frequently wishes to use to enable him to solve his own problems or to instruct others. Speaking roundly, I may say that every physician should take five journals. Every medical teacher and every specialist should take a dozen. Every Medical Journal Club and small library should take from 25 to 50; every large medical library should take from 150 to 300; and the national collection in each country had better take them all, say 1,000 or more. A physician can almost always procure the current text-books and monographs at a comparatively small expense; but for the journals, transactions, and reports he must largely rely upon some general library.

Not that the current monographs, or the old classics, or even the inaugural theses and dissertations will not be wanted occasionally, or that these should not be collected and preserved as opportunity offers; but that by far the greater portion of the fund, unless it exceeds five thousand dollars a year, had best be devoted to the procuring, binding, and preserving of the periodical literature of medicine, and to the making it promptly accessible to those who wish to use it. Few persons except those who have had some practical experience in library management have any idea of the time and labor required to do all this; it seems to the majority that two persons at most ought to be able to do the work required in a library of thirty or forty thousand volumes receiving two or three hundred journals, and that the money which would be required to pay for additional assistants had much better be used in buying more books.

This, however, is a mistake. In a library of the scope and purpose which that of the New York Academy of Medicine should have, the whole time of one skilled, careful assistant should be exclusively occupied with the periodicals and reports, and it will require his utmost efforts to see that the files of these are kept complete and readily accessible.

Your library ought to receive three hundred current medical journals and at least seventy-five series of transactions and reports, and the task of keeping these complete and in proper order is not a small one. Moreover, such a library as this should obtain and preserve a complete series of documents relating to local medical history. It should have complete files of the reports, scheme of organization, regulations, catalogues, etc., of every medical society, of every hospital, dispensary, or asylum, of every medical school or other institution in its own city, county, and State. Most of these are only to be had by writing for them at the time of their publication; they are commonly said to be very cheap and to be had for the asking, but I think you would be a little surprised, if you tried to get a complete set for one year only, to find how much it had cost for stationary, clerical labor, and postage to accomplish it. Therefore, I say, give your librarian a fair amount of clerical assistance to enable him to do all this, and to keep his catalogue up to date, to keep his accounts in order, to spare ten minutes to hunt up some references for this member, ten more to write to the Washington branch for another member, fifteen more to hunt among the duplicates for material to exchange, etc.

With regard to the library of the Surgeon-General's Office in Washington, which I have referred to as your Washington branch, I have to report that it is in fairly good condition and ready to assist you in the future as it has done in the past. There are some things which it can not do, however. A year or so ago the editor of a leading New York medical journal printed a humorous editorial notice to his subscribers to the effect that he could not undertake to furnish medical bibliography and abstracts of medical literature, and those who wanted them should apply to the librarian of the Surgeon-General's Office, who would supply them for a suitable pecuniary consideration. The publication of this note gave me a very realizing sense of the power of the press as an advertising medium, and also of the existence of an unfilled want among the medical profession of the country. Within ten days after this editorial notice appeared I received a goodly number of letters requesting summaries of the latest and best literature on measles, on the treatment of disease of the spinal cord, on ptomaines, on orthopædic surgery, on the death-rates of civilized countries for the last ten years as compared with those a hundred years ago, etc., with, in each case, an estimate of cost.

Now, I have not the time to do work of this kind on de-

mand, and I do not take pay for what little I can do for my friends who make reasonable requests. There were two or three young physicians in Washington who undertook this kind of work when they had time, charging about a dollar an hour for it; and at times they were kept busy. One of them has gone away, one of them has now so much practice that he only makes abstracts for his own use, and one of them has nearly gone out of the business. No doubt we shall be able to find others in course of time who will take their places and to whom I can refer requests of this kind, which I am always glad to do if possible; but I can not promise that it is always possible. A definite question in medical bibliography, so far as giving references is concerned, we try to answer; if it involves over ten minutes' clerical work in copying I have it done by some one not connected with the library, and this must be paid for; but special researches and the making of abstracts and translations can not be done by the librarian or his assistants, although we will do our best to find persons who can and will do it.

Dr. Andrew, in the last Harveian Oration, says that he regards the *Index Medicus* with special horror. So do I. I wish we could cut it down to one fourth its present dimensions, but we can not. As it is, we omit nearly one third of the matter that fills the pages of three fourths of the medical journals, as being not worth indexing.

At the present rate of increase of printed medical literature, the investigators of fifty years hence are likely to have a hard time of it, and we must do what we can to provide for their needs. The great bulk of such literature is almost useless within ten years after it is printed, the case and operation records having the most permanent value; but there are very few books or pamphlets which are not at some time called for by somebody, and hence there are few which the Academy's librarian can reject, although there are many that he should not seek for.

My business to-night, however, is not to advise but to congratulate, and I beg pardon for having wandered from the point. I have watched for the last ten years with great interest the efforts which have been made here to secure a permanent home, which is so desirable for all medical societies in large cities, and yet which is thus far possessed by so few in this country; and I know something of the struggle it has cost, and how much you are indebted to the energy, perseverance, and tact of a few of your members, and especially of your last three presidents, for the marked success which has been achieved. And as this success, while of prime importance and interest to yourselves, is also a substantial contribution to the means of advancement of scientific and practical medicine everywhere, you have a right, and these men have a right, to the thanks of the medical profession all over the world for this achievement, and in behalf of that profession I offer them.

(*To be concluded.*)

Proceedings of Societies.

RICHMOND ACADEMY OF MEDICINE AND SURGERY.

Meeting of September 23, 1890.

The President, Dr. W. W. Parker, in the Chair.

(*Reported by Dr. James N. Ellis, Richmond.*)

Placental Disease as a Cause of Premature Labor.—Dr. John N. Upshur read a paper with this title, in which he said that the sparse literature on placental pathology made a discussion of the lesions of this viscus one of no little difficulty, and it was only by clinical observation and legitimate deductions from such clinical facts that we could arrive at conclusions of a practical nature—these being proved only by the successful issue of treatment founded at best upon theory suggested by these clinical facts. Reflections on this subject were suggested to the writer by a case which was made the text of his article and which was one of great interest and concern to him. The welfare of whole family connections, based upon pecuniary considerations, or the domestic happiness which often centered in fruitful issue, could not be overestimated.

He had been called to see Mrs. B., August 5, 1888, in her third pregnancy, advanced to the fourth month, aged twenty-nine, blonde, health always robust. She had lost two children at the beginning of the seventh month, being attended by one of the leading physicians of this city. Careful inquiry had failed to elicit the history of any imprudence on her part—a jar, a fall, or any tangible cause for the premature labor. The history of both the first and second pregnancies was identical with the third. There was no swelling of hands or feet, no headache, and careful analysis had failed to disclose the presence of albumin, or any functional derangement of any organ whatever.

She was enjoined to be as quiet as possible, avoid going up and down stairs, to keep early hours, and given tincture of the chloride of iron and uterine sedatives, and watched most carefully and anxiously. Soon after entering the sixth month the movements of the child had become each day more feeble and irregular, and she had begun to complain of a weight in the hypogastrium; motions of the fœtus had ceased and labor had come on at the beginning of the seventh month, October 28th. Labor was easy and rapid. The fœtus had cried feebly once or twice; presented a swollen appearance with more or less sclerotic condition of skin, cord empty of blood, placenta firmly adherent, requiring nearly three quarters of an hour to remove it. The uterus had contracted well and firmly. The placenta was very soft, pale, and anæmic—so soft as to drop to pieces by its own weight, or a portion of it.

The patient had become again pregnant early in January, 1889. Carefully reflecting on the condition of the placenta and the history of the two previous pregnancies and deliveries, the speaker had concluded that the cause of the death of the fœtus and of the premature delivery was a latent endometritis, stimulated to active progress by pregnancy and the implantation and development of the placenta—the inflammatory condition extending to the placenta, producing fatty change, cutting off the circulation of the fœtus, and consequent death so soon as the pathological change had progressed far enough. All history of syphilis could be absolutely eliminated, because both parents were exceedingly anxious for issue, and he was confident that he had elicited from the husband the whole truth as to the history of his sexual life. He had once had a mild gonorrhœa previous to marriage—suspicion here, you say, of urethral chancre; but, if so, why did he not have bubo and secondary symptoms at the time, and tertiary symptoms succeeding? None of which he had ever had, nor had he ever had any syphilitic treatment. The woman herself was absolutely above reproach. So soon as the speaker was informed of the occurrence of pregnancy for the fourth time he put the patient upon the most active alterative treatment of the bichloride of mercury, red iodide of mercury, and chloride of gold and sodium, varying these alteratives, and keeping up the treatment for six months. The patient also drank lithia water freely. He desired in this connection to especially commend the chloride of gold and sodium as an alterative. Its action in the dose of one eighth of a grain to one twentieth of a grain in combination

with extract of one of the bitter tonics was in many respects similar to that of the iodide of potassium, but he believed it had a special influence in modifying inflammatory conditions of the endometrium, and in his hands had certainly been productive of very great benefit. The patient had progressed beyond the usual danger point and was delivered safely at term. Labor was easy and rapid, child a magnificent specimen and free from every blemish, was now more than a year old, and had been singularly exempt from the usual infantile maladies. The placenta was healthy.

The speaker said that Galabin spoke of inflammation of the decidua which might arise from previous endometritis existing prior to conception, and it might exist in the vera, or reflexa, or serotina. He said the study of inflammation in this situation was difficult, because the cell proliferation of the decidua was analogous to that which took place in the inflammatory process; it was the inflammatory process in the decidua serotina which chiefly affected the placenta. Symptoms of this trouble were soreness and tenderness over the uterine globe, but might be entirely absent. The same author above quoted said that fatty degeneration might be partial, and then the fœtus might be born alive, but that, when "extensive, it may directly kill the fœtus by cutting off the supply of blood." Parvin (*Science of Obstetrics*) spoke of the distinction made by Dr. R. Barnes between fatty degeneration and fatty metamorphosis: "The former begins in the living, the latter is found in the dead tissues." In Cazeaux and Tarnier was found the expression of doubt as to the ability to fix the symptomatology of this lesion, there being only evidence of uterine congestion, manifested in some cases by weight in the lower part of the abdomen and pain in the loins and down the thighs. But these symptoms might be present when other placental lesions existed. There might be apoplexy, sclerosis, syphilitic disease, cancer, etc. It was not pertinent to the subject under discussion to consider these, nor would time or space permit. He had been led to consider the subject from its present standpoint because of the success attending the treatment of repeated premature delivery, based upon the theory enunciated, and because, in the light of such success, it might point the solution to some case of similar difficulty.

Supplementary to his paper and in reply to questions, Dr. Upshur called attention to Galabin's opinion that a peculiar pinkish color of, and the presence of watery gummata in, the placenta was evidence of syphilitic disease of that organ. But he was satisfied of the absence of any syphilitic taint in the case reported. The success of the alterative treatment might also suggest syphilis. But he had seen decided improvement in simple endometritis from the exhibition of the chloride of gold and sodium. He ascribed the good result in the above-cited case principally to the use of that salt. The general health of the patient was good.

Dr. Hugh M. Taylor was reminded of a patient who had lost her first three children at about the eighth month. In all of these pregnancies preventive treatment had been adopted. Subsequently she had had three children; no preventive treatment had been attempted, and all of the last three children had been born alive, strong, and robust. He thought we sometimes credited medicine with alterative influence which it did not deserve.

Dr. Moore did not think that conception could take place in a uterus which at the time of connection was the subject of corporeal endometritis. The leucorrhœa consequent upon such diseased condition effectually impaired the vitality of the spermatozoa, or by its flow washed the ovum from the uterine cavity. But, even if conception took place, it was impossible for gestation to progress safely, and abortion or miscarriage resulted. Where conception took place in a healthy uterus and endometritis subsequently occurred, the pathological changes consequent upon inflammation of the endometrium precluded the possibility of a continuation of pregnancy to term. Where the neck only was involved, conception and delivery at term might occur. But, when both neck and body were diseased, non-conception was the rule. Placental disease proper was frequently secondary. Various morbific conditions of the blood brought about abortions—such as continued or the eruptive fevers and syphilis, especially secondary. In tertiary syphilis the patient frequently went to full term. Congestions and other interferences with the circulation occasioned by flexions or versions produced fatty or amyloid degeneration, or general uterine contraction sufficient to detach the membranes. Retroflexions were especially fruitful in these bad results.

Dr. Upshur did not think that the failure to abort, in the case of his patient, could be ascribed to coincidence as suggested by Dr. Taylor. He referred to other cases of endometritis not connected with pregnancy in his practice that had been benefited by this treatment. A case yielding to iodide of potassium or bichloride of mercury did not necessarily imply syphilitic taint. It was not common for conception to take place where there was an existing endometritis, especially of the cervix; but where there was latent endometritis before marriage it might be developed by pregnancy. This patient had had a dysmenorrhœa before marriage, but had not been treated for it, as conception took place so quickly he did not have the opportunity.

Convulsions following the Ingestion of Unsound Oysters.—Dr. Upshur had been recently called to see a lady of usually robust health. He had found her with decided trismus—spasmodic contraction of both flexor and extensor muscles of hands and of the lower extremities; spasms, both violent and painful, lasting several minutes, and excited by a slight draft or current of air. There had been no wound to give origin to suspicion of traumatic tetanus, and no probability of her having obtained strychnine. But it seemed she had eaten a few raw oysters the day before, when the weather was warm. The convulsions had been accompanied by choleraic symptoms—nausea, vomiting, and purging, but no collapse. He had administered morphine hypodermically and chloroform by inhalation, and had further controlled them by twenty-grain doses of bromide of potassium every two hours. He was satisfied that the convulsions were due to eating unsound oysters.

The President reported a case of convulsions in a mulatto child whom he had relieved of an attack of nausea a month before by the use of carbolic acid. There had been four or five convulsions daily, accompanied by a profuse flow of saliva. Suspecting worms, a vermifuge had been administered with negative result. He had then given an emetic of sulphate of zinc without relief. The fourth day he had been present during the convulsions, which were confined to the upper portion of the body and the upper extremities. He thought them due to ingestion of some insoluble substance. The patient had been rubbed with croton oil along the spine last night, and was better this morning.

Dr. Hoge thought the convulsions due to some preputial trouble.

Angina Pectoris.—Dr. Edward T. Baker reported a case of this affection supposed to be caused by depressed fracture of the skull. He had called to see a white man aged thirty; height, six feet two inches; weight, two hundred and five pounds; very muscular; occupation, striker in a blacksmith-shop. Prior to 1884 (when he had received the injury to his head) he had not seen a day's sickness in his life. This injury had left him with a depression on the left side of his head, on a level with the top of and an inch posterior to the margin of the ear, and

one inch and a quarter from the tip of the mastoid process. The depression had measured an inch from the upper to the lower margin, and an inch and a half from the anterior to the posterior margin. He was confined to his bed eight months after receipt of the injury. After he was able to go about he had had an attack of angina pectoris, and had had as many as three a week since that time. Sometimes he would not have one for a month, when they would return with increased severity. He had been treated by a number of doctors without relief. He noticed that he had had more attacks, and they had been much more severe in character, since he had had *la grippe* last March. A stethoscopic examination of his chest had revealed the heart sounds normal, but a little weaker than seemed in keeping with his fine physique and general strength. He had some dyspeptic symptoms, for which elix. lactopeptine was prescribed. The speaker's objects in reporting this case were—

1. To get the opinions and advice of the older members of the Academy in regard to the advisability of using nitrite of amyl in this case. As the patient noticed that when he got very warm, and especially when he lowered his head in stooping, it gave him pain in the back of the head just above the neck, and that he would become unconscious unless the upright position was immediately resumed; as amyl produced about the same effect (vertigo, dizziness, and flushing of the face—in other words, temporary hyperæmia), was it not advisable to use it, and thus substitute unconsciousness due to congestion of the brain for angina pectoris?

2. Could we attribute the angina pectoris to the blow on the head which might have fractured the inner table of the skull, and, by irritation of that portion of brain, so interfered with the action of the pneumogastic nerve as to cause the heart trouble?

3. Could he not be operated on and the depressed bone raised from the brain, and thus relieve both conditions?

He said that he had been repeatedly told by physicians that the wound was too low down to be operated on. He was now taking sodium bromide, compound spirit of ether, and aromatic spirit of ammonia three times daily, and every two hours when threatened with attacks. The speaker further said that the attacks were not more frequent in the recumbent position or at night; mind clear, and that he thought there was chronic congestion or inflammation about the brain.

The President thought it a clear case for operation.

Dr. Upshur had seen a case that, in regard to epilepsy, was similar to Dr. Baker's. The skin over the temple had been cut by a falling timber. No ascertainable depression. Epileptic attacks—two or more daily—had soon followed, dulling mental action. The skull had been trephined, and upon the inner table of the button of bone removed had appeared a deposit of callus, indicating that there had been fracture. There had been no convulsions for a week succeeding operation, but at the end of that time he had fallen forward on his face—dead. Another case was that of an inmate of the Central Lunatic Asylum. He had been struck on his head with an axe in 1862, and a piece of bone had been driven on the brain. The patient had become violently insane, but there had been no epileptic convulsions. He had been trephined by Dr. Hunter McGuire in 1869. He had been perfectly rational upon recovery from the operation, and had taken up the thread of events from the time he was struck, the intervening period being a blank. Subsequently he had died of cerebritis.

Dr. Hugh M. Taylor had recently had a case somewhat similar to that cited by Dr. Baker. A railroad employee had received an injury in the same region, remaining unconscious for thirty-six hours thereafter, when his mind had cleared. There was no fracture of the skull diagnosticated. He had suffered pain over the frontal region; the left eye had been blood-shot and protruded, evidently from some cerebral lesion. He had continued this way for two or three weeks. In six weeks he had begun suffering from vertigo, increased pain, and depression of the cerebral functions, amounting almost to coma. This had been followed by a discharge of pus from the ear and "Cheyne-Stokes" respiration. Abscess of brain, probably due to depression, had been diagnosticated. After consultation with Dr. C. W. P. Brock, it had been decided to trephine, but the patient had died on the night before the day selected for operation. Post-mortem examination had revealed cerebral abscess containing an ounce of pus. The speaker was satisfied that he should have trephined.

Another case of abscess of the brain was reported by Dr. M. D. Hoge, Jr. Two weeks ago he had seen in consultation a workman with suspicious history of previous syphilis. He had been semi-comatose for two days. There was abscess of the skin on the right frontal eminence; left leg paralyzed; bowels and bladder under complete control; respiration accelerated; pulse very quick and small; temperature, 104° F. On account of the feeble and uncertain condition of the heart, it was decided not to trephine. He was put upon drachm doses of potassium iodide every four hours. Sixteen hours later he had died, paralysis having rapidly extended to all four extremities. The skull was trephined at post-mortem at a point selected in discussing operation the day before; dura mater pale and thickened, a smoothly-lined pus cavity lying beneath of the size and shape of a guinea-fowl's egg, occupying the right frontal lobe, and filled with thin, offensive fluid. There was no apparent communication between the external abscess and the interior of the cranium.

Dr. Taylor thought the cerebral abscess might have been secondary, as subpericranial suppuration might find its way into the skull by extension along the venous sinuses leading into the cranium. A cerebral abscess not infrequently occurred as a result of phlebitis of the diploic veins.

The President, in calling attention to the occasional presence of serious brain trouble without significant symptoms, spoke of a patient who had suffered for some days with frontal headache and then had fallen suddenly dead. The post-mortem had revealed an ounce of pus just back of the frontal sinus. Cerebral abscess was a frequent cause of death in children. He had seen a child with bluish boils about the neck which he had opened, and he had been surprised to hear of death from convulsions on the next day. The post-mortem showed extensive softening of the brain, which had evidently been diseased for some time. Another case was that of a ten-year-old boy whose skull had been fractured by a wagon-wheel passing over it, death occurring several weeks subsequently. His mind had been clear to within a few hours of death. The post-mortem had shown disorganization of the whole top of the brain. Query, Where was the seat of intelligence? The speaker then spoke of several cases of atypical typhoid fever that had recently come under his observation in which there had been no heat of the skin, no furred tongue, and no loss of appetite for fluids, attended with emaciation and prostration. One had terminated in fifteen, another in thirty days. In treating typhoid, the points to be guarded were the brain, lungs, and bowels. He gave an abundance of good milk and toddy. He had given a girl one quart of whisky every day for six weeks. He thought it greatly reduced the temperature. For the diarrhœa he gave a mixture of turpentine, kino, paregoric, and bismuth.

Dr. J. W. Henson reported a case of fever which he was unable to classify. There had been at first griping pains over the abdomen which had been somewhat distended, but no tenderness or pain on pressure. Fever had run a regular course of

morning remission and evening exacerbation. Morning temperature from 99° F. to 99°+, evening from 100° F. to 100°+; occasionally entire absence of fever for days. Pulse rapid and weak. The patient had suffered greatly at times from cardiac weakness and a sense of impending death. He had been revived by stimulants. There had been slight delirium at times. He had suspected lung trouble, but physical examination had given no evidence thereof. The patient had been treated at first by mercurial purgative, followed by quinine, with a tonic of iron and arsenic and dilute nitro-hydrochloric acid; milk diet, and later whisky in frequently repeated doses. The patient had fattened while in bed. Suspecting local influence as a cause, he had sent her to the country for the month of June. She had menstruated regularly till the beginning of sickness, when she had missed one or two periods. There had been no evidence of scrofula. She was first taken sick last December, and still had fever, but was otherwise apparently well.

Dr. W. S. Gordon had recently been consulted by a lady just from a malarial district where she had been nursing a typhoid patient. She had fever and had been taking large doses of quinine. In each week she would have fever for four days and be free from it the succeeding three. Examination of the lungs had revealed a slight subcrepitant râle at the apex of the right lung. She had no cough, but was emaciated; no history of previous pneumonia. She had been put on creasote and whisky, followed by improvement. She had been sent to the country, and on return there still had been slight fever.

The President was satisfied that phthisis might exist in its earlier stages when there was no cough and no evidence of its presence was furnished by physical signs; and he thought that Dr. Henson's patient had consumption.

Reports on the Progress of Medicine.

HYGIENE.

By S. T. ARMSTRONG, M. D., Ph. D.

Public Disinfecting Chambers.—According to *Le Mercredi médical* of July 30, 1890, the municipal council of Paris has voted for the establishment of disinfecting chambers for the use of Hôtel Dieu, Charité Hospital, Necker Hospital, Laennec Hospital, Broussais Hospital, and the two lying-in clinics. At the Beaujon Hospital the chamber is to be used by the public as well as the institution. The total cost will be 120,947 francs. The advantages that these free disinfecting establishments offer needs no comment.

Disinfection by Gases.—Dr. J. E. Gaillard, in a Paris thesis of 1889, reports a number of experiments on the germicidal action of nitrous-acid and sulphurous-acid gases on pure cultures of different micro-organisms (*Staphylococcus pyogenes aureus*, comma bacillus, bacteria of charbon, bacillus of green diarrhœa, typhoid fever, pneumococcus, etc.), and also on inferior organisms contained in the atmosphere of a room. He concludes:

1. Nitrous-acid gas is a powerful disinfectant, but difficult to employ practically on account of its corrosive action.

2. Sulphurous-acid gas has an evident microbicidal action on germs in the air.

3. Sulphurous-acid gas should be employed to disinfect contaminated localities, in the strength of forty grammes to the cubic metre of air.

4. The action of sulphurous-acid gas is exercised very energetically in the presence of moisture, hence the precept to saturate disinfecting chambers with steam.

Permanent Aeration of Rooms by Open Windows.—Dr. Nicaise, in the *Bulletin de l'Académie de méd.* of the 25th of February, 1890, refers to Raulins's suggestion, in 1752, that tuberculous patients should live in rooms with the windows kept open, and to Dettweiler's application of this method of treatment—with regulated and generous alimentation—at Falkenstein. At this place 132 positive recoveries had been obtained in 1,022 tuberculous patients, while 110 more patients were apparently cured. Nicaise, in order to ascertain the value of this method of treating tuberculosis, experimented for several months on the temperature of the external air and that of a room with a window constantly opened to the southeast, the window blinds being shut at the close of day. He ascertained from minimal temperature readings, taken each day, that the temperature of the room oscillated between ten and fourteen degrees centigrade. The author explained the maintenance of the constant temperature by the stirring up of heat during the day, and its emission during the night, by the walls of the room and the objects that it contained. [In his paper, however, he makes no mention of the germicidal influence exercised by the free sunlight in the room; that is probably as beneficial as the aeration and temperature regulation.]

Cancer of the Stomach in Switzerland.—Dr. H. Hoeberlin, in the *Deutsches Arch. f. klin. Med.*, xliv, p. 461, finds that cancer of the stomach is encountered twice as often in Switzerland as in Berlin or Vienna. Among 2,500 persons, one will die each year from this disease; 1·85 per cent. of all deaths are due to it; and from 1877 to 1886 cancer of the stomach increased in the proportion of 100 to 165 for men, and of 100 to 158 for women. General cancerous diseases are more frequent in Switzerland than in Prussia, Vienna, or England, women being more subject to such diseases than men. Cancer of the stomach bears the proportion to the total mortality from cancer of 31·9 per cent. in women and 51·8 per cent. in men; and in Zurich it is twice as frequent in women as cancer of the uterus, while in Vienna the contrary is true.

The influences of season, profession, city life, country life, or the wealth of the individual, seem to have no effect in preventing the disease. But it does seem that the use of cider and of acid wine increases the predisposition to cancer of the stomach. Heredity seems to have some influence, eight per cent. of the patients observed having had parents die of cancer of the stomach. Possibly a bad condition of the teeth influences the development of gastric carcinoma.

Cancer in Normandy.—Dr. Arnandet, in a paper in *La Normandie médicale*, April, 1890, makes a study of the proportion of deaths from cancer in some cities (Rouen and Havre) and communities in Normandy. He believes that there is an excessive mortality from cancer in certain regions in Normandy, and that the existence of the disease in certain foci and its recurrence in certain houses, as well as its epidemic character, point to the action of a local cause that is external to the organism. The great predominance of cancer of the abdominal viscera over cancerous affections of other localities proves the importance of the ingesta as exciting causes. Water and cider, that is largely used as a beverage in this locality, should be judged as possible causes as well as habitations. Houses where deaths from cancer have occurred are contaminated and should be rigorously disinfected.

An Examination of the Soil of Old Cemeteries.—Dr. L. de Blasi and Dr. G. Russo Travali have, according to the *Revue des sciences médicales* for July, made an examination of the bacteriological characteristics of the air and soil of the old cemeteries of Palermo. They found no greater number of micro-organisms in the air and soil from these places than in other localities in the city. Without counting mucedenes, they found twenty-seven species of schizomycetes, none of which were pathogenic. This observation confounds the prevalent idea of the noxiousness of the soil of old cemeteries.

The Frequency of Tuberculosis in Northern and Southern Countries.—In a general way it has been accepted, says Dr. G. Wykowski in the *Viertelj. f. gericht. Med.*, p. 339, 1890, that the mortality from phthisis pulmonalis is diminished in high northern latitudes and increased in southern countries. Yet in the most northern cities of Finland and Norway the mortality from tuberculosis is from 2·3 to 3·4 in a thousand living inhabitants, while in southern Italy it is but 1·7 in a thousand living; so statistics refute current opinion. If the statistics of the different parishes of Norway are compared, it is evident that the mortality from tuberculosis decreases as we go north; but in Fin-

land an increase in the mortality is noted in the northward movement. In the north of Finland, the population of which is 3 per cent. Laplanders, the mortality from tuberculosis is 2·7 to a thousand living, while in the same latitude in Norway, with a population of 85 per cent. Laplanders, the mortality from tuberculosis is 1·8 to a thousand. The decrease of tuberculosis in the latter country corresponds to the decrease of a mining and industrial population and the large proportion of people living in the open air—the same reason that exists for the difference in the number of cases of tuberculosis in the city and country.

To compare these figures with those of Italy, we find only in northern and central Italy the mortality from tuberculosis reaching 2·3 to a thousand living inhabitants, while in southern Italy it is only 1·7 to a thousand, in Sardinia 1·4, and in Sicily 1·3.

The Prophylaxis of Tuberculosis at Meran.—According to the *Revue des sciences médicales* for July, the municipality of Meran has passed a police regulation forbidding the use of spittoons made of anything else than porcelain, stoneware, or enameled metal, in taverns, restaurants, boarding-houses, or rooms occupied by strangers. The spittoons must contain only pure water, and must be cleansed daily. The use of sawdust in spittoons is prohibited.

The Distribution of Tuberculosis in Switzerland according to Altitude.—Dr. L. Schroeter, in the *Viertelj. f. gericht. Med. und öffentl. Sanit.*, li, 1889, p. 125, has studied the official statistics for eleven years—from 1876 to 1886—having had at his disposal numerous and exact documents. He concludes that in Switzerland the annual mean of deaths caused by pulmonary tuberculosis is 2·31 to a thousand living inhabitants; there are 105 deaths from tuberculosis in a thousand deaths from all causes. The greatest mortality from tuberculosis is in the cantons of Appenzell, Bâle-Ville, and Geneva; the lowest mortality is in Uri, Haut-Unterwald, and Schaffouse.

At an altitude of 200 to 400 metres there are 112 deaths from tuberculosis in a thousand deaths from all causes; at an altitude of from 400 to 700 metres, 105 deaths from tuberculosis in a thousand; at 700 to 900 metres, 106 deaths in a thousand; at 900 to 1,200 metres, 92 deaths in a thousand; above 1,200 metres, 71 deaths in a thousand.

Tuberculosis is endemic in all Switzerland. The mortality from this disease does not decrease either regularly or proportionally in comparison with what is believed of altitude. The mortality is regularly increased as the proportion of the industrial population increases; for equal altitudes, the industrial districts have a greater mortality from tuberculosis than the agricultural districts.

The Influence of the Level of Subsoil Water on the Diffusion of the Typhoid Bacillus.—According to the *Revue des sciences médicales* for July, 1890, Dr. L. de Blasi has recently published at Palermo the results obtained with inoculations of the typhoid bacillus in cylinders of soil, with necessary subsoil water levels. He concludes:

1. That the typhoid bacillus preserves its vitality in the soil at the end of eighty-six days.

2. That it is not diffused in the soil more than ten centimetres above the position in which it is placed.

3. But, in depth, it is found from twenty to thirty centimetres below the site of inoculation, this diffusion depending upon the level of the subsoil water.

The Influence of Sand Filters on the Water of Zurich and Berlin.—According to the *Revue des sciences médicales* for July, Bertschinger has formulated the following conclusions regarding the Zurich water supply:

1. The filtration by sand that is employed at Zurich produces an essential purification of the water of the lake.

2. Normally the filter furnishes water free from germs; yet, some time after filtration, the water will contain a small number of bacteria.

3. The swiftness of filtration (at least within the limits of three to twelve metres a day) has no influence on the character of the water—that is to say, filtered water gives the same results by chemical analysis, and contains an equal number of bacteria, whether filtration has been more or less rapid, the water of the lake yielding all its cryptogamic germs to the superior layer of sand.

4. At first, after cleansing the filter, its action is not normal, and consequently the filtered water then contains a much greater proportion of germs, though the cleansing of the filter does not exercise any appreciable influence on the quality of the filtered water.

5. When the filter ceases acting, the filtered water is for some time richer in bacteria than usual. The multiplication of bacteria is due to the water being undisturbed. But a chemical analysis of the water standing in the filter is in nowise different from that of water fresh from the filter in ordinary working.

6. Neither chemical analysis nor bacteriological examination shows any difference in the action of a filter that is exposed to light and air from that of a covered filter. Each of these filters retains in the same way the bacteria of the unfiltered water.

Dr. C. Fraenkel has made a small filter of sand similar to the large filters that have been proposed for the purification of the water at Berlin. He has demonstrated that this filter allows the ordinary bacteria of water, as well as pathogenic bacteria—such as typhoid fever and cholera bacilli—to pass. The number of micro-organisms that pass through the filter is in proportion to the number of micro-organisms that are in suspension in the water to be filtered. There seems to be some dependence on the rapidity of filtration, the number of micro-organisms increasing when the filtration is rapid. It is at the beginning and end of the experiment that these organisms are most increased; at the beginning, because the filter does not act efficiently, and at the end, because the pressure is considerable, and perhaps because the bacteria are reproduced in the filter during the experiment. Therefore the general confidence in sand for water filtration does not seem to be absolutely justified.

Charbon in Hair-workers and Tanners.—In 1887, says the *Gaz. hebd. des sci. méd.*, a commission was appointed in France to study charbon and the measures that should be employed for disinfecting skins, hair, and horns. The dried hair of cows and horses is imported in large quantities from South America, and it is packed in bales of four to five hundred kilogrammes; as soon as a bale is opened, the hair is picked over by hand. Preliminary steam disinfection of the hair causes such deterioration in its quality that this process can not be employed, consequently the hair-worker runs considerable risk. The risk run by tanners is evident, and from 1878 to 1889, inclusive, forty-nine persons with charbon were admitted into the St. Denis hospital. The conclusions are presented—

1. The manipulation of French hair and skins entails less danger to-day than heretofore.

2. There is very great danger in working in similar imported products.

3. It is necessary to study the question of the disinfection of foreign products utilized in such industries, and it should be referred to the approaching International Congress of Hygiene.

Freire's Yellow-fever Inoculation.—Dr. G. M. Sternberg, in a paper on this subject in the *Journal of the American Medical Association*, July 26, 1890, reviews the statistics published by Freire to support the value of his method of protection from yellow fever by inoculation. Freire maintained that, of 1,183 persons inoculated, 18 died of yellow fever; that is 1 in every 66 vaccinated. Dr. Sternberg, estimating that one half the population (400,000) of Rio de Janeiro had been protected by previous attacks of the disease or long residence in the city, accepts Freire's figures that the total mortality from yellow fever in that city was 2,386, and thus demonstrates that in the susceptible population of 200,000 only 1 in 84 persons died of the disease. Dr. Sternberg concludes that a careful analysis of published results fails to prove that Freire's inoculations have any prophylactic value.

Distinct Species of Comma Bacilli in Cholera.—In the May number of the *Indian Medical Gazette* Surgeon-Major D. D. Cunningham—who recently reported failure to obtain any evidence of the presence of cultivable comma bacilli in the discharges of cholera patients at certain seasons of the year—reports that in certain cases that in general symptoms, character of discharges, and fatality are undoubtedly cholera, he has obtained three very distinct species of comma bacilli. These species are not, as a rule, associated with each other, are independent of the character of the cases from which they are obtained, but are found in all cases coming from the same locality.

Morphologically there seems to be no great difference, but physiologically the rate of growth varies in rapidity; and on potatoes one forms a thick, slimy, creamy stratum, with a smooth, glistening surface

and prominent lobulated margins. The color at first is pale-yellowish, becoming gradually primrose, and ultimately strong yellow, at one stage of the growth resembling a stratum of thick pus; the smell is yeasty and vinous. The second species develops as a thin, diffuse stratum, at first white, later brown. It is not shiny or prominent, and the odor is mawkish and choleraic. In the third species the growth is at first grayish-white, later pale buff; it is prominent and dry-looking, and raised in wrinkles and folds.

Microscopically, the first species shows at first distinct commas, but in a short time is composed of micrococcoid bodies with a few enormous commas. The second species has more persistent commas of considerable thickness. In the third species the commas are imbedded in a tough, zooglœar mass that stains deeply with gentian violet.

With cultivations in nutrient broth, nitric and sulphuric acids (as ordinarily employed to develop cholera purple) with the first species produce flocculation that is soon deposited, and the development of the purple tint. In the other species the flocculation is persistent for many hours.

The author believes that the conflicting statements made by European observers regarding the spore formation of Koch's comma bacillus is caused by a different species of this bacillus being observed by the different reporters.

Vital Statistics in France and Germany.—The *Journal of the American Medical Association* of July 26, 1890, makes an interesting comparison of the vital statistics of France and Germany. In 1888, in Germany, there were 376,654 marriages, 1,828,379 births, and 1,209,793 deaths. In that year in France there were 276,848 marriages, 882,639 births, and 837,867 deaths. In Germany the births exceeded the deaths by 618,581, while in France the excess of the former was only 44,772. In considering such statistics it is necessary to remember that, while the area of the two countries is almost the same, yet, notwithstanding the vaunted economy of the French, their country supports a population averaging a little more than 187 to the square mile, while Germany has a population of a fraction over 224 to the square mile. The statistics of some years past show that there is an increase in the birth-rate in Germany and a decrease in France; three children is the average to each family in the latter country, the voluntary limitation of offspring being due to a desire to provide for the future of children.

In Canada the French descendants believe in *crescite et multiplicamini;* according to the *Lyon médical* for August, the Government of the province of Quebec has announced the intention of giving one hundred acres to every head of a family who is father of twelve children. Two farmers have, each, 35 children, one has 34, and one 21, and one gentleman has baptized his thirty-seventh heir. Families of twelve are not rare; so the transplanted French stock retains its vigor.

The Effect of Tropical Countries on the Number of Red Corpuscles and the Hæmoglobin.—Dr. Marestang, in the *Revue de médecine* for June, gives the results of his examinations of the blood of sixteen soldiers while on a voyage from France to New Caledonia. The men were from twenty to twenty-two years of age, mostly from Breton, at sea for the first time, the voyage occupying three months and a half, of which two and a half were in the tropics. The examinations were made at intervals of fifteen days during the period of the voyage, the percentage of hæmoglobin being estimated by Melassez's hæmochromometer. An average of the examinations shows that in fourteen the number of red globules increased from 500,000 to 1,000,000 to the cubic millimetre, while in two it diminished 120,000 and 228,000 corpuscles. The proportion of hæmoglobin was increased in twelve men from from 1 to 5 per cent., in three men it decreased from 0·5 to 1·5 per cent., and in one the proportion remained stationary.

He abandoned the idea that the increase was due to the sea air, because he found in seventeen convicts who had resided from five to ten years in New Caledonia an average of 5,770,000 red corpuscles and 14·35 per cent. of hæmoglobin, while at Tahiti, in twelve marines that had resided there for two years and three quarters, he found an average of 6,758,000 red corpuscles and 14·2 per cent. of hæmoglobin.

These results demonstrate that in Europeans living in tropical countries, who have not incurred disease, there is an increase of red corpuscles and of hæmoglobin. Maurel, at Guadeloupe, has arrived at the same conclusion regarding the corpuscles.

This increased activity of the hæmatopoietic functions constitutes a simple phenomenon of supply; the excess of corpuscles and of hæmoglobin, the fixative elements for oxygen, has no other end than that of furnishing to the organism the quantity of that gas that is necessary for the normal accomplishment and regulation of its functions—to counterbalance, in another word, the influence of the meteorological elements. Between Europeans living at home and those living in the tropics there is, from a physiological point of view, this difference: that, while with the former N globules and hæmoglobin are required for the absorption of oxygen, with the second class $N + n$ is required.

The Regulation of Prostitution in England and France.—The crusade against the contagious-diseases act in England has resulted in what would have been expected. From 30 to 50 per cent. of troops, quartered in garrison towns, are on the sick list with venereal diseases, while during the enforcement of the law the proportion so affected was very small.

In France, M. Commenge recently stated at a meeting of the Academy of Medicine of Paris that he had collected the statistics of the number of diseased prostitutes found in the decade from 1878 to 1887: First, among women registered by houses or cards; second, among those women that—though registered—were the object of more or less frequent arrests, and constituted a special class under the name of *femmes du dépôt*; third and lastly, among the uninspected, or women that lived by clandestine prostitution.

He had carefully authenticated his figures, and the results obtained were very interesting. The women registered by cards were paid 305,799 visits; there were found 3·12 cases of syphilis in 1,000, and 3·06 in 1,000 were affected with diseases other than syphilis. Of the women registered in houses, there were recorded 503,712 visits: 2·7 cases of syphilis in 1,000 were found in this class, and 2·52 cases in 1,000 of diseases not syphilitic. To the *femmes du dépôt* 76,740 visits were paid; 23·96 persons in 1,000 were syphilitic, and 14·46 persons in 1,000 visits were affected with non-syphilitic diseases. To the uninspected women 2,704 visits were paid; 166 syphilitic persons in 1,000 were found, and 134 in 1,000 had diseases other than syphilis.

These figures demonstrate the greater proportion of syphilis among the uninspected prostitutes, and the danger of the propagation of syphilis is greatest among them. In the language of Dr. Commenge, the poorer women are inspected for those that are diseased, and the latter are not returned to circulation until cured. The unregistered, on the contrary, continue to sow syphilis without anything being done to restrain them.

It is only by the accumulation of such statistics that the fanatical sentiment against the regulation of prostitution can be overcome and the health of innocent women and children protected.

The Regulation of Prostitution.—Dr. Thiry, of Brussels, read a paper on this subject before the International Medical Congress (*Le Mercredi médical*, August 20th), in which he states that prostitution is not only due to moral depravity, but principally to a physiological function that is absolutely dominant at a certain age; whether desirable or undesirable, it is a necessary evil; its excess may be repressed, its dangers may be limited, but it can not be extirpated. He holds, with certain fathers of the Church, that, if it were possible to suppress prostitution, society would be afflicted by libertinism; there would be a reproduction of the syphilitic epidemics of Rome and Naples; there would be an increase of seduction, of illegitimate births, of adultery, of rape, of abortion, etc. This necessary issue of human passion should be under surveillance and regulated, like food, sewers, and collections of filth, to which Parent Duchatelat compares it. Inspection is the sole way to protect prostitutes and those that use them from disease. In certain countries it is ignored on the fallacious theory that it antagonizes liberty and the dignity of women. What is the liberty that exists to the prejudice of public health? And is not the woman always free to abandon her vocation? Another error is to regard prostitution as a crime. The following propositions were submitted: 1. The regulation of prostitution is necessary to restrain the propagation of venereal and syphilitic diseases. 2. Prostitution that attracts attention by the frequenting of streets, promenades, and public places, being the most powerful cause of propagating venereal diseases, should be forbidden. 3. Women that are known to live habitually as prostitutes

should be registered and given sanitary visits. 4. The registration and sanitary visits should be authorized under the safeguard of guarantees that should always and everywhere protect the honor and the dignity of the individual. 5. The sanitary visits should be frequently and conveniently made.

Dr. Kaposi, of Vienna, considered there were two ways to combat prostitution: by measures that depended on administrative regulation, and by those of a scientific nature—the first a matter of governmental authority, the second a matter for physicians. The Austrian Government in 1889 adopted measures for the surveillance of acknowledged and clandestine prostitution, and for taking preventive and disciplinary measures against those that communicate syphilis. In all the universities the study of dermatology and syphilography is obligatory, because all physicians may have occasion to decide on the existence of syphilis in domestics. Each prostitute receives a book containing a descriptive list, photograph, and a copy of the laws relating to prostitution and prostitutes. No one under sixteen can be registered, and minors or married women must receive authority from their legal guardians (parents or husband); persons affected with organic or constitutional diseases or deformities can not be registered. Sanitary examinations are made twice a week, by a competent physician, in an appropriate place; all diseased women are put in hospitals, primary syphilitic cases being quarantined for three months, and kept under treatment two years. Clandestine prostitutes are treated in the same way, though they may be treated by their own physician.

Dr. Nesser thought the examination should be made for gonorrhœa and syphilis; while the examination of the genital organs, anus, and mouth was certainly excellent, it was not absolutely reliable. He thought a cervical leucoderma was a certain sign of syphilis; and in one year, at Breslau, he had examined 572 prostitutes, and found the gonococcus in 216 patients in the urethra, uterus, or both.

Dr. Felix, of Bucharest, Dr. Drysdale, of London, Dr. Heinzinger, of Gröningen, and Dr. Crocq, of Brussels, opposed Thiry's conclusions, particularly the limitation of prostitution to a few public houses, branded by Felix and Heinzinger by the name of moral contagion. Felix held that in the future we should instruct, without false modesty, the pupils of higher classes in colleges regarding the dangers to which they were exposed, and instruct them primarily on the various prophylactic measures. The criticism was made that this desideratum was possible, but would not the "professor of coitus" be a veritable innovation for the end of this century?

The Hygiene of the Dissecting-room.—The once familiar dissecting-room, with its wooden floor and plastered walls redolent with the foulness of years of service, its wooden tables supporting cadavers in various stages of decomposition, and an atmosphere that remained a reminiscence during an entire professional career, has in many medical schools given place to composition or tiled floors and wainscot, with excellent ventilation and stone tables that are non-absorbing. In some institutions better methods are in vogue for the preservation of the cadavers; but, in view of the character of much of the material and the possibility of the student acquiring at his work the foundation of constitutional disease, it would seem desirable to pay more attention to the hygiene of the dissecting-room.

In the *Gaz. hebd. de méd. et de chir.* of August 23d the method in use at the Paris School of Medicine is given as follows:

Many cadavers are lost in warm weather in Paris, because the preservative injections are given too late; they arrive at the school in a state of putrefaction for which nothing can be done. This fact is understood when it is remembered that bodies are retained until the last minute in order that they may be reclaimed. If the dead-house attendant would give, at the end of the first twenty-four hours, an injection into the carotid artery of a ten-per-cent. solution of chloride of zinc, not only would it delay putrefaction, but also prevent the discoloration of the skin of the face that makes recognition of the dead sometimes impossible.

On arriving at the dissecting-room, the body apertures are cleaned and washed with a stick, and the entire body is washed.

The body should not be carried by the hands and feet, thus disarranging the position of the muscles, but placed on a movable table of the height of a dissecting-table. The body is numbered with a fatty printing ink that can not be washed off, the number being registered with the name, age, and hospital. In winter the cadaver should remain in a room heated to 20° or 25° C., to soften the fat, that is coagulated by cold and prevents the penetration of the injection.

The best injecting fluid is ten per cent. of phenic acid in glycerin; in winter five per cent. will do. Alcohol may be used with an equal quantity of the glycerin, making the solution more penetrating. For economy a saturated arsenical solution may be added to the injection; two thirds of the ten-per-cent. glycerin with one third of arsenical solution will suffice. The preservative would be better if composed of half a litre of chloride of zinc to half a litre of the arsenical solution; five litres would be required for an ordinary subject. The injection may be made by the carotid, or, better, the aorta, and should be given slowly with moderate pressure, using either a syringe or an elevated receptacle.

The room for storing cadavers should be dry, of constant temperature, and scrupulously clean and free from odor.

Dissected material should be cremated, and in every way the dissemination of micro-organisms from the cadaver to the student be prevented.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

THE DANGERS OF EXCESSIVE PHYSICAL EXERCISE.

A LECTURE DELIVERED BEFORE THE YOUNG MEN'S CHRISTIAN ASSOCIATION OF WASHINGTON, D. C.

BY E. L. TOMPKINS, M. D.,
RESIDENT PHYSICIAN OF THE HAMMOND SANITARIUM, WASHINGTON.

GENTLEMEN: The subject before us this evening is one of great importance and interest to all of us—to you as athletes and gymnasts and to me as a member of the medical profession. We are very intimately associated, for when you indulge in such sports to excess you generally come to the physician for assistance. Just here in the beginning of my remarks I do not wish to be understood as one who condemns physical exercise. I greatly approve of it, and congratulated myself on hearing Dr. Rosse's address last Friday evening, but I can not join with Dr. Rosse in "combating the howl against the imaginary danger of athletics set up by some of our shallow and pretentious brethren." I know that so much exercise is fraught with great danger, and some of these "shallow and pretentious brethren" I wish to quote later on. When we speak of excessive physical exercise we are bound to embrace every form of work, such as running, walking, lifting, straining of any kind, gymnastics, foot-ball, base-ball, and the like.

The word exercise, in its physiological sense, means that quantity of activity of every anatomical part of the body which will require that part to perform its function. The popular definition of exercise at the present time is, I think, contraction of the voluntary muscles. That is perfectly proper, if taken with moderation, but nothing seems of interest now unless in competition with some one else. I have endeavored to separate the dangers of excessive exercise into four divisions—viz.: the danger to the brain, to the heart, to the lungs, and muscular system.

We will first take the brain. In looking over the literature on the subject, I have, unfortunately, not been able to gather very much in which the brain was directly affected by physical exercise, except in the gymnasium, where a man hangs by his legs with head downward and has what is commonly called "rush of blood to the head." We very frequently hear a person say he was too tired to sleep; this was probably due to an excessive supply of blood to the brain, and if it goes on for any length of time he will have a disease of the brain called cerebral hyperæmia. One of the worst cases that I have seen lately was that of a man from North Carolina; he was a farmer by occupation and said he did nothing but walk over his farm from daylight to dark, looking after his crops; he was in the habit of going to bed directly after he got his supper—about eight o'clock—never read anything but the Bible occasionally, and had nothing in particular to worry him; and yet he couldn't sleep, and had a bad attack of hyperæmia of the brain, which was probably indirectly brought on by excessive physical exercise. Great mental work and great physical work are entirely incompatible, for the human system has only a certain quantity of nerve force to be expended, and if it is all used up in muscular exercise there will not be left any for the brain. It is all very well for boys and young men to exercise moderately, but when they become men they are intended for something higher and better. Moreover, only a small amount of exercise is needful for health.

Some enthusiasts on the subject of physical culture maintain that it is not only necessary for health, but even for life. Now, it is pretty certain that exercise is not absolutely necessary for life. A physician from Jacksonville, Fla., a friend of mine, tells me of a woman that he knows personally who has been in bed for thirty years, and is likely to live a long time yet. She is not sick, but simply declared she never was going to get out of bed again. I have known of several persons myself that have remained in bed ten and fifteen years. After a while they got tired of staying in bed, and, without any treatment at all, got up and walked. One of them is as healthy to-day as I am and goes everywhere she wants to. Then look at the many prisoners who are closely confined. The majority remain fairly healthy without much exercise. A few fail in health, and I think it is due as much to the mental worry as to the close confinement. All prisoners are confined, one probably as closely as the other, and yet those whose health fails are always spoken of in the newspapers, they are so few.

Second. The effect on the heart is well marked, and a great many physicians have written on the subject. Every one knows how his pulse quickens; he can feel his heart beating through his chest, has palpitation and short breath when he runs up the steps or takes any violent or unusual exercise; these are merely outward symptoms. Dr. F. A. Mahomed, pathologist to St. Mary's Hospital, made observations on Weston, the noted pedestrian, during the last week of his five-hundred-mile walk. By means of a sphygmograph he was enabled to measure the arterial tension every day. He discovered that on the first day Mr. Weston began his walk with a perfectly normal pulse, and during the first two days the tension was somewhat reduced, during the next three days the tension gradually rose, and attained its highest point on the fifth day of his walk. His temperature was reduced simultaneously with the increase of arterial pressure. On the sixth day he took a long rest and sleep, his temperature went up, and the arterial pressure was reduced. After resting thirty-six hours and living well, he regained his normal pulse and temperature. The observations made on the same man by Dr. Flint, of New York, were practically the same. These observations merely went to prove what Dr. Mahomed had stated elsewhere—that exercise produced two important and opposite effects on the circulation, according to the condition of the person under observation. In persons unaccustomed to exercise and not in proper condition it reduces the arterial tension and increases the temperature. This explains how very warm one gets and how freely he perspires, and how soon he becomes exhausted; his heart palpitates and is actually weaker when he is unaccustomed to exercise. "When this is carried to extreme, syncope, from anæmia of the brain, may occur, the brain being robbed of its blood

by the unduly increased requirements of the muscles and sudden failure, by paralysis, of the action of the heart. . . . On the other hand, the arterial tension may be increased. There are several theories for the cause of this. One is that the impaired nutritive power in the tissues interferes with what has been called the chemico-vital capillary power and causes capillary obstruction. Another theory is that there is contraction of the arterioles, due to irritation of their vaso-motor nerves by an irritable and exhausted brain. . . . And still a third cause is that the heart is excited to a degree above that required for the effectual circulation of the blood, the influx of blood into the vessels being in excess of the afflux by the capillaries, thus raising the tension." This condition was well marked in Taylor, one of the competitors of Weston, and slightly so in Weston, who was probably in better training. Variation of tension in this direction is accompanied by reduction of temperature. It increases the work required from the heart, and failure of that organ to meet the strain thrown upon it gives rise to dilatation. This is known by a number of symptoms, the chief ones of which are breathlessness, oppression at the præcordia, vertigo, coldness of the extremities and reduction of the temperature of the body generally, pallor and anxiety of the face, dilatation of the pupil, smallness and irregularity of the pulse, and irregularity and shallowness of respiration." Very often we hear of some old gentleman, or even lady, who drops dead after some unusual exercise, such as going up the steps fast or running after a street-car. The majority of street-car companies have cars enough which follow one another closely, and if we are not in time for one we should wait calmly for the next and not run such enormous risks; but such is the desire with every one at the present time to get ahead of somebody else that he can not wait. Dr. Hammond has collected seventy cases of death during the last ten years of men running after a street-car and dropping dead in the street. These deaths were purely due to the inability of the heart to meet the strain required of it. Some of you might say that these men had heart disease of some sort before, and that their deaths were due to that, and they probably did; but that only goes to prove that not every one is in the proper condition to take violent exercise of any sort. I think every one who wishes to indulge in athletics should be thoroughly examined by a physician and pronounced perfectly sound beforehand, and even then there should be a competent instructor who should tell him what to begin with, just how long he should exercise, and not let him overtax his strength in any way. Lifting heavy weights is not the best way to get strong, and yet a great many young men think that in order to increase the size of the muscles and be considered stronger than any one else they must lift some weight far too heavy for them. I know a man, about twenty-four years old, in Atlanta, Ga., who was really quite strong, but he offered, for a wager, to lift five hundred pounds from the floor and put it on a table. While he was straining with this weight he felt a very sharp pain in his back; that pain has never left him, although it has been about two years, but his spinal column has become curved in two places; he also has a disease of the spine called Pott's disease; his spinal cord has also become affected, which has brought on paralysis of both legs, and he has been in bed several months now, and the probability of his ever getting well is rather uncertain. Dr. Hammond told me of a case that came under his observation. A man tried to raise a window-sash which would not go up; he overstrained himself, felt severe pain in his back, and was paralyzed in both legs immediately.

The cases of hernia that are caused by lifting and jumping are numerous, and I will speak of them later. Dr. Morgan, in his book called *University Oars*, relates some very interesting cases. He was confident that the bad results of excessive exercise in rowing frequently were never heard of, so he took the names of 294 who rowed in the inter-university race in a given time, and wrote letters to them asking them to give accounts of themselves as to whether they suffered from any disease that could be attributed to rowing. He got replies from seventeen of them, some written by themselves and some by their friends or relatives. The following are extracts from their letters: A said that while rowing in the college races he suffered from bad cold and pain at the angle of his chest. In spite of this, he continued to row, and it gradually passed off. The following spring he had a chill while traveling in a stage coach, his breathing became affected, and an attack of inflammation of the right lung ensued. This illness was protracted, and he was assured by his physician that he had permanent induration of the top of the right lung, which had set in when he was at college. In this case, if the injury did not result from overexertion in the boat-race, it was due to the fact that such exertion was undertaken at a time when from indisposition the man was not in a fit state to row. The next case is that of B, who, in referring to his own case, says: "I am unfortunately an illustration of the evils which may be induced by overexercise. I am forty-one years of age and quite obsolete from an hypertrophied heart, which has gone on to dilatation and its consequences." He then goes on to tell how he was in the habit of spending his time then, which does not concern us in this paper. The next is C. His report is as follows: "About a week before the race I felt a pain in my left arm as if I had gotten rheumatism, and it became rather stiff until after the race, and then severe inflammation set in in the elbow joint, followed by abscesses, and, after three months in bed, pieces of bone came away, and I had the elbow joint excised, and the arm is still stiff." His friend confirmed his remarks by stating that he was sure that that particular race did not bring on all the inflammation that ensued, but that he had had no rest from hard labor for two years, besides going in for every race that took place, and consequently entered upon the training for this big race in an already exhausted state. Dr. Morgan then quotes the cases of six persons that have died—five from consumption and one from heart disease—and their nearest relatives wrote that more or less grave suspicions were entertained that the diseases that carried them off were originally induced by their overexerting themselves in rowing during their college days. One of them, D, died soon after of consumption. It was said of him that his illness and delicate health were sup-

posed certainly to have arisen originally from the bursting of a blood-vessel, through his exertions in rowing, either in the practice for the inter-university race or in the race itself. One of his fellow-oarsmen said: "D was a very fine oar, but he always gave me the idea of being an unsound man; he was always pallid and looked ghastly after a long and severe turn. I often used to think him likely to break down in training." The next case was that of E, who died of consumption. One of his relatives, in speaking of him, said that he had not died until long after he had given up rowing, but he had never doubted that his failure of health and early death at the age of twenty-nine years were due to boat racing, as no other member of his family had broken down in the same way. Another oarsman, who died of some affection of the chest which was not stated, was spoken of by his father as follows: "I could not feel assured that the excessive training and racing could be undertaken safely by a growing and undeveloped constitution, not robust, though elastic and strong." Another person, G, died of consumption. One of his friends writes that his physique was not such as to staud the wear and tear of these contests. His exertions were of a more than ordinarily trying character, for he had participated in many severe races both on the Thames and at Henley, and he was a man, almost of all men, the least likely to spare himself. The eighth case was that of H. He also died of consumption in a few years after the race. It was not known whether he died from overexertion or not. J was injured by rowing. He was found dead in his bed some time after he had stopped rowing. His friends said he was an enthusiast in the sport, and they had often seen him exhausted. All thought his exertions brought on his death. K recounts his case as follows: "I rowed in a great many races—in several while yet a boy at school. When I rowed at Putney I was twenty years of age. I experienced soon after this severe pain in the region of the heart and was thoroughly done up, and was forbidden to walk up hills and told that unless I was very careful I should never get over it. However, I did take care of myself, and have been recovering health and strength ever since. Though I was never incapacitated from ordinary employments, still I was prevented from engaging in any violent exercise from the certainty with which it brought on the old pain at the apex of the heart." He then goes on to relate some of his occupations and to speak of his children, and finally concludes thus: "At the same time the conclusion I should have come to in my own case is that I overexerted myself when too young, and, had I begun when I left off growing or a year or two later, I should not have experienced any evil effects." Another man who overworked his strength was L. In speaking of his health he uses these words: "I have for the last three years suffered much from having overexerted myself, and have only just begun to go up hill again. I should not think of attributing my ill-health to the university race when I know what a very small proportion the energy expended, and the exhaustion consequent on it, can bear to that due to the combined effect of other races in which I have rowed and other forms of violent exercise in which I have overtaxed my strength."

M also would appear to have done too much. His brother says of him: "I have no doubt M. seriously injured his health by overexertion in rowing and running; he was an enthusiast in everything he undertook and imagined nothing could hurt him, but soon after leaving the university he fell into bad health, and died some eighteen years after the race." He attributes his ill-health to overexertion. It was the continuance for too great a length of time of boat-racing that did him so much injury.

N is also believed to have suffered. One of his relatives writes: "After the university race he fainted away, and it was two hours before they could restore him. It was always thought that the part he took in the race injured a small vessel at the heart; previous to that he was always a strong, muscular man. Eleven years after he was suddenly taken sick, and died in a few days."

O speaks of his health in the following manner: "When I went to the university I was healthy and strong, and my weight was a little over twelve stone. I began rowing at once in my college boat and also in the university crew, both at Putney and Henley. I lost almost a stone in weight during my rowing career, but did not feel any ill effects until after my last race, when I became very weak, with pain in my side. One doctor whom I consulted attributed these symptoms to the overexertion and hard training I had undergone, but considered there was no serious mischief. I recovered from this attack in time, and since then have enjoyed fairly good health, though I have gradually lost weight and become very weak. Three years ago, after taking a little more exercise than usual, I brought up a great quantity of blood. This, my medical man said, came from my left lung." He then states that he had no return of hæmorrhage until the following spring, when he had another attack of bleeding from his lung. After that he had great difficulty in breathing, and was much weaker than before, although he had no more hæmorrhages.

The next three persons, P, Q, and R, in giving accounts of themselves, declare that they were in good health as long as they kept up such violent exercise, and only suffered from their respective troubles after they had taken up a sedentary mode of living. The question might be raised, though, whether or not these troubles were not the result of such excessive exercise, and probably would have appeared much sooner if they had not quit and commenced a sedentary life. I have consumed rather more time with the subject of boat-rowing than I intended, but I wished to show particularly the bad effects on the heart and lungs that this kind of exercise produces when it is carried to excess.

Dr. Charles W. Cathcart, in his article on Physical Exercise: its Use and Abuse, which appeared in *Health Lectures* and which is published by the Edinburgh Health Society, goes quite extensively into the subject. He enumerates quite a number of accidents—such as fractures, especially of the collar-bone, dislocations, sprains, and other injuries that take place during the different games, especially foot ball—and while he encourages these games, if taken moderately and by persons who are fitted for such exertion, he says that overgrown lads should be careful how they exercise violently, as they are particularly apt to suffer.

But I wish to quote him *verbatim* in his remarks relating to brain work and physical exercise: "Only one other point occurs to me as specially deserving our attention just now, and that is the relation of brain work to exercise. It must be the experience of most men that the fullest amount of brain work and of muscular exertion can not be carried on simultaneously without injury to whoever is bold enough to try the experiment; only a certain amount of nervous energy is available in the system. There is a reserve fund of nervous energy for explosive purposes, and when this is once exhausted it is rarely got back. This may be expended either chiefly in muscle work or chiefly in brain work, or in a proportionate combination of both, but not in the fullest possible amount of both at the same time. Therefore, when extra brain work is called for, we should not expect from our bodies the full amount of muscular exertion that they are capable of. Sufficient be it for the time if we get enough exercise to keep us in active health, and, when we again have an opportunity, we can very soon bring our muscles up to their wonted standard. But, since this preponderance of brain work in our modern life is so frequently unavoidable, it becomes all the more necessary that, when the frame is still in its plastic condition, it should be stamped with the best possible physical impressions. The conditions necessary to attain this are not incompatible with sound mental training and earnest brain work, but it can not go along with that mental worry and and labor which ought only to be found, if at all, among those who have reached maturity and have passed into the active duties of life."

He adds further on: "I must, however, add a word of caution to those who, in after-life, are unfortunately obliged to follow sedentary occupations. They should be careful how they return to their former activity. If caution be not used, the exercise will do them more harm than good, so that it behooves us to be as careful as we can, always to begin gently and increase by degrees."

It is very certain that great mental work and great muscular work are incompatible; and I remember well, when I was a student at the University of Virginia, that those students who did more hard study than any of the others found that a brisk walk of about two miles a day gave them plenty of exercise to keep them in health, but did not fatigue them so much as to prevent them from studying; and those others who took leading parts in base-ball, boat-rowing, foot-ball, and all kinds of athletics, were, with a few exceptions, not the hard students, but rather the reverse. In fact, a great many young men enter colleges, such as Harvard, Yale, and Princeton, apparently only to be members of the base-ball club or foot-ball club or boat crew, and seem to think that a greater honor than to graduate in their studies. I know of a young man who went to the university just to join the base-ball club. Professor Edward Parkes has calculated that walking one mile on the level, unloaded, is equal to lifting 17·67 tons one foot; but if loaded with a knapsack weighing sixty pounds, the work done is equivalent to lifting 24·75 tons one foot.

Moderate labor in the open air is the most healthy for the average man who engages in it. Now, according to Professor Parkes, the daily work performed by him will probably average from 250 to 350 tons lifted one foot, which will be equivalent to a walk of nine miles, and a healthy adult can take this without incurring risks of overfatigue; but allowance must be made for the other exertion incurred by the ordinary business of life, which in many cases would cause a considerable reduction. We all know that every action of the living body is attended by chemical changes in the composition of its tissues, and that force is liberated by such changes, either in the form of heat or motion. The heat, of course, maintains the temperature of the body. This force is generated by the combination of the food taken into the body and the oxygen which is taken in while breathing. Carbonic-acid gas is evolved by the action of the oxygen on the carbon, one of the food products; therefore we breathe in oxygen all the time and breathe out carbonic-acid gas.

The more work or muscular exercise that is performed, the faster and necessarily shorter the respirations. The physiological effects produced by muscular exercise are increased action of the lungs and heart.

Professor Parkes has given a concise table showing the effects exercise has on the absorption of oxygen and the evolution of carbonic-acid gas, which shows that on a "work day" eight ounces and a half of oxygen were absorbed in excess of that on a "rest day," and that thirteen ounces in excess of carbonic acid were evolved on the work day, although the so-called "work day" included a period of rest, the work being done only during working hours and was not excessive.

Therefore the more work, the greater the amount of oxygen required, and therefore the greater number of respirations, and with it necessarily the greater number of expansions and contractions of the chest. It has been proved that the faster the respirations, the smaller is the quantity of carbonic acid exhaled at each expiration. Now, the average number of respirations in the adult is about eighteen to twenty per minute; but with violent exercise, such as boat-rowing, running, foot-ball, and so on, they are greatly increased. It might be said that although the quantity of carbonic acid is smaller in each respiration, if the number of respirations should be large enough, it would accomplish the same result by exhaling all the carbonic acid. This would be true if the power of maintaining strong and rapid respirations continued; but soon the chest muscles of respiration give out and the inhalation and absorption of oxygen diminish, and carbonic acid accumulates in the blood, producing what is called "out of breath." The man is practically poisoned by carbonic-acid gas. Many instances of this are seen in the running and rowing races, where the man falls flat on his face, and perhaps faints, just as he almost reaches the goal. He, as a rule, soon recovers if allowed to remain perfectly still and get a few long breaths. Oxygen is rapidly taken in, and the blood that was made impure by the accumulation of carbonic acid is properly aerated. It is claimed, and rightly so, that exercise improves a weak heart and also weak lungs; but this is true when exercise is taken moderately and regularly, so that the arteries can get accustomed to the increased action of the heart. In ex-

cessive exercise the action of the heart is increased much more and has to send an extra amount of blood to all parts of the body, so that the arteries, which are taken so suddenly, do not allow the blood to pass through, and there is a blockage. The impure blood, laden with carbonic acid and coming from the parts of the body in action, is not sent on quickly enough to the lungs to be replenished.

This blockage up of the blood does not take place alone in the arteries going to the lungs, but throughout the entire body; so, unless we begin very gradually and with due preparation, instead of benefit, much harm may be done which is permanent.

I am told that only a few nights ago one of your number fainted just after going through some sort of violent exercise. Instead of quickening the vital changes, they are stopped almost entirely, and the blood may accumulate in the heart and produce dilatation, which is a very serious disease. Therefore it is very dangerous for men who lead sedentary lives to start out suddenly in the summer on their vacations to climb mountains, row boats, run or walk long distances, and they are frequently worse off after their vacation than before.

Moderate exercise increases the appetite; but no doubt you have frequently heard people say they were too tired to eat. It is probably due to the fact that the bodily powers are fatigued and there is impairment in the power of being able to take food. If this continues, the health is seriously affected. It is said that the exhaustion of muscles from overwork is due principally to want of oxygen to burn the carbon elements which supply their force, and also from the accumulation of the products of combustion. This of course results from the heart and lungs refusing to work vigorously enough. The advocates of gymnastics maintain that the muscles are enlarged, the chest expanded, the heart and lungs strengthened, the appetite increased, and good health generally maintained. That is true enough; but if the muscle is exhausted its nutrition is seriously impaired, which may not be recovered from for many days. Instances of this are not merely loss of power, but peculiar, irregular pains and cramps, tremors and contractions. It is well known that if the leg of a frog is amputated and a current of electricity applied to the muscle itself, it will contract immediately, and if the stimulus be applied again, it will contract the second time, and continue on in this way, provided the stimulus is not applied too often and too rapidly. If it is, the muscle soon begins to contract less each time, until it is no longer affected by the electricity; but if, even in that condition, the stimulus be applied to the sciatic nerve, it will immediately contract as before, until finally the muscle is exhausted and will no longer respond to the stimulus, even when applied to the nerve itself. And so in health, during excessive exercise, the brain is the stimulus to the nerve, but soon the muscle is exhausted if made to work too long and too fast. Not only that; although exercise increases the size of the muscles, then if the exercise is continued too severely and for too long a time, it is not only exhausted, but begins to atrophy or waste away. Such cases are sometimes seen in the ballet dancers. Some of the most active men sometimes have a disease called progressive muscular atrophy—a disease which, if not absolutely incurable, is rarely cured. We had such a case as that only a short while ago at the Sanitarium. The man was of tremendous frame and had led a very active life. He used to brag that he could jump off a train moving at the rate of twenty-five to thirty miles an hour and not feel it. He couldn't imagine how it was that his muscles were all wasting away. These "living skeletons" that you see in dime museums are generally victims of progressive muscular atrophy or another disease which resembles it in some respects, called anterior polio-myelitis. Virchow has taught that a disease called valvular endocarditis is more common in the left side of the heart than the right, in consequence of the great muscular force of the left ventricle, so that when aortic disease has led to hypertrophy of the left ventricle, changes in the mitral valves become frequent, and the increased force with which the mitral valves are closed induces those nutritive changes called chronic endocarditis.

And, as Fothergill says in his interesting paper, styled Strain in its Relation to the Circulatory Organs, in connection with heart disease, that which is more interesting and of greater importance is the change in the aortic valves themselves and the causes of that change. Placed at the base of the aortic column, they are closed by the aortic systole on the arterial recoil. Every increase in arterial tension will close the semilunar valves with greater force, and this causes valvular disease of the heart. He goes on to say that "aortic valvulitis is met with under two totally different circumstances—(1) in the gouty individual with chronic kidney trouble, (2) in the young and robust who pursue certain forms of labor. At first sight there seems but little in common between the action of gout poison and that of the laborer; still the morbid processes induced by these two totally different causes are, apparently, not only identical, but even the manner of their causation is the same. In both cases the aortic valves are exposed to violent closure from increased arterial recoil, and in both cases valvulitis from strain results." All of you who know anything about anatomy will remember how the arteries run along close to the muscles, sometimes within the muscle, or under it, or between it and a bone, or over or under a tendon. When an athlete is straining every muscle in the gymnasium, those muscles are in a state of contraction, in which condition they are hard and press on different arteries and obstruct the circulation. The heart, continuing to pump away with increased vigor, distends the arteries, and of course there is an augmented recoil; the heart first becomes hypertrophied, and then follows valvular disease of the heart. You have all seen how the veins stand out on the wrists of men in the gymnasium when they are trying to perform some difficult feat which requires great muscular force. It is because the circulation is obstructed. A person who is suffering from a mitral disease of the heart frequently causes an atheromatous condition of the pulmonary artery and its branches. Thus we have valvulitis and atheroma of the arteries at the same time, which is seen frequently. The causal association between atheroma and strain has been shown by Dr. Clifford Allbutt and Dr.

Moxon. The latter says (1) that what is called atheroma of arteries is a subinflammation of various degrees, of which the lower degrees end in fatty degeneration of the coats, along with the inflammatory products, and (2) that the determining cause of the occurrence of this change is mechanical strain.

Dr. Fothergill, at the end of his article, gives a *résumé* of his opinions, which I wish to quote word for word: "1. Changes in the right heart are induced by increased strain when the mitral valve is diseased. 2. Mitral valvulitis often results from aortic disease, in consequence of the mitral valve being forcibly closed by a hypertrophied ventricle. 3. Aortic valvulitis, as well as atheroma, is intimately associated with mechanical strain. 4. Certain dyserasial conditions in which these affections are common merely favor the occurrence of such changes. 5. Women are much less subject to aortic valvulitis than men are, and this is due to their pursuits rather than to their sex. 6. The importance of mechanical strain in the production of disease in the circulatory organs is scarcely yet sufficiently appreciated."

Hewetson says: "I hold that nowadays few men can train hard for athletics and at the same time excel in mental study without overstraining their physical or nervous power. This evil of attempting to combine the two is undoubtedly gaining ground in the present day." He reports two cases that came under his observation. One was that of a man who was running in a severe contest, felt sudden pain in the chest, followed by exhaustion; on examination, there was found organic disease of the heart. The other was that of a leading athlete who had embolism at the base of the brain.

I remember a person that I saw in one of the hospitals of New York. His history was as follows: He had had previously a severe attack of inflammatory rheumatism, which had caused organic heart disease. During some unusual exertion, one of the little vegetations which grew on the valves of the heart was washed off and carried along with the current of blood until it reached the capillaries, where it could not proceed farther. This is what is called cerebral embolism. In this case it produced paralysis of one side of the face and tongue, so that he could not articulate distinctly and could eat with difficulty. Also one whole side of his body was paralyzed.

Dr. Edward Smith read a paper before the Royal Medical and Chirurgical Society on The Influence of Labor on the Treadmill on the Pulse and Respiration. He calculated the quantity of air respired in the sitting position and then on the treadmill. During the exertion the quantity of air inspired was increased more than four-fold rate, the respiration was increased two thirds, the depth of inspiration two and a half, and the rate of pulsation two and a half times. He then proceeded to consider the effect of this kind of exercise on the system, and showed that the excessive exercise of the heart and lungs must lead to phthisis, asthma, emphysema, congestion of various organs, with a thinning or thickening of the walls of the heart, and with persons of diminished vital capacity of the lungs and a weak heart the effect must be sooner serious.

I believe that cattle-men have quit driving their cattle and sheep long distances to market on account of the different lung troubles they develop on the way simply from being overdriven. A friend of mine in Texas, who is a large cattle-raiser, told me that he had stopped altogether, and always sent them to Chicago on trains; that it paid much better in the end.

Dr. Stork, in the *Edinburgh Medical and Surgical Journal*, reports a very interesting case of what he calls overdriving in the human subject. A man was driving some cattle that broke and ran. He ran after them, and it was a long time before he succeeded in getting them together again. By that time, though, he was thoroughly exhausted himself; he had pain in his chest, began to cough and spit up bloody sputum, had great difficulty in breathing, pulse very fast, and high temperature—in fact, all the symptoms of inflammation of the lungs. The overdriving in this case is analogous to racing and rowing. I wish to say just a few words in regard to hernia, or rupture. There are cases, of course, that are congenital, and a few are caused by other things than strain, but the great majority of cases come from overstraining, particularly that of lifting heavy weights. In looking over works on hernia, you will find that the majority of cases belong to the laboring class, and that men have it more frequently than women. I knew a young physician in New York who was lifting a heavy woman from the operating-table; he felt a sudden pain in the inguinal region, which continued, and he soon found that he had a hernia. There are certain games that are particularly apt to cause hernia; one is called the "tug-of-war," and you, as gymnasts, of course know what it is. The cleats that were used for placing the feet against, in order to pull harder without slipping, I believe are being done away with.

There used to be a lifting-machine in most of the gymnasiums called the health-lift. A very competent instructor in athletics told me that that machine had ruptured more men than any other one thing that he knew of. It belongs to me in this paper only to point out the dangers of excessive exercise, but I do not think it would be out of place for me to say a word or two in favor of this particular Young Men's Christian Association. As I understand it, it is intended to bring together young men who perform a Christian work by doing good to others and at the same time elevate themselves to what is noblest and best in this life. The gymnasium is only one feature of the association, and it seems to me to be very complete. You have a good instructor, and I don't see how, under his guidance, you can have many accidents. I have seen Mr. Sims go through what he calls the "dumb-bell body exercise," and it gives thorough exercise to every muscle in the body. He tells me that he never uses a dumb-bell in this particular exercise that weighs more than two pounds, and that the Indian clubs that are swung should weigh only four or five pounds, instead of twenty-five and thirty, that I have seen in other gymnasiums. And now, gentlemen, I would like to call your attention to the aged couple, both of whom were centenarians, who were found by a Boston reporter at meridian sun resting under the shade of one of the grand oaks of Massachusetts. Of course he interviewed them as to

the cause of their longevity. No doubt, gentlemen, he went there for that purpose. The reply he received was significant: "We led a peaceful life and spent a great part of our time in the open air."

Gentlemen of the Young Men's Christian Association, a peaceful life with moderate exercise in the open air will surely be conducive to health and happiness.

Note.—Since writing the foregoing I have clipped the following from the Pittsburgh *Dispatch*, which speaks for itself: "Of the thirty-two all-round athletes in a New York club of five years ago, three are dead of consumption, five have to wear trusses, four or five are lop-shouldered, and three have catarrh and partial deafness. As far as general health and longevity go, the dry-goods clerk outdoes the athlete."

THERAPEUTIC PRINCIPLES GOVERNING THE SELECTION OF CARDIAC MEDICAMENTS.

TWO LECTURES DELIVERED IN THE COURSE ON THERAPEUTICS AT THE MEDICAL DEPARTMENT OF DARTMOUTH COLLEGE. *October, 1890.*

BY SOLOMON SOLIS-COHEN, A. M., M. D.,

PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS, PHILADELPHIA POLYCLINIC; VISITING PHYSICIAN TO, AND LECTURER ON CLINICAL MEDICINE AT, THE PHILADELPHIA HOSPITAL, ETC.

LECTURE I.

GENTLEMEN: Having studied the powers of the principal agencies employed to influence therapeutically the heart and circulation, we shall now devote two lectures to the study of the more important principles which should guide us in the application of these agencies to the treatment of morbid conditions: whether with a view to bring about recovery, or merely to prolong life or promote comfort. The first lecture will be more especially concerned with laying the foundations for our subsequent study; and that these may be sufficiently broad and deep, it will be necessary to treat of matters which at first sight may seem remote from our immediate theme. But, as I have throughout all our studies endeavored to show, the observations of the physician must be comprehensive. Not that in seeking far afield he should neglect what lies close at hand, but neither must he so contract his gaze and converge his eyes that the tip of his nose shall fill his farthest horizon.

The interdependence of vital functions is so great that no part of the body can be successfully treated, when diseased, without due consideration of its relations with all other parts and with the body as a whole. At the bedside quick observation and prompt decision are often demanded. There is no time for elaborate reasoning. But, in order that we may be prepared for the emergencies of practice, we must in the lecture-room and study fortify ourselves with knowledge. We must here ponder our facts and set in order our thoughts, so that we may have ready for use a store of matured conclusions.

Therefore I crave your patient attention while I pass in review some familiar facts, in order that by repetition they may become impressed upon our minds, and that, by grouping them about a new center, a new phase of their important relations may be made clear.

The value of rest, local and general, in the treatment of diseases of the heart or other pathological conditions affecting the circulation was treated at length in the earlier portion of our course, when hygienic therapeutics was the subject of consideration. Still, a few words in reminder of certain general principles may not be inappropriate at this time.

We have seen it to be an absolute rule, not only in biology but throughout all nature—a rule to which there can be no exception, because it depends upon the very constitution of nature—that the period of repose is the period of repair; the period of activity is the period of waste. Rest means construction, upbuilding; a coming together of matter, with storing up of energy. Action means destruction, downthrowing; a tearing apart of matter with liberation of energy.

Throughout nature we have that continual rhythmic alternation of attraction, repulsion; construction, destruction; upbuilding, downthrowing; which in the study of life-processes we call the *metabolic rhythm*, applying to its two phases the Greek terms, *anabolism* and *catabolism*.

Upon the preservation of this rhythm—that is to say, upon the maintenance of the normal relations between anabolism and catabolism, rest and action, repair and waste—depends the *structural and functional integrity* which constitutes the health of the various tissues of the body, and of the great aggregations of tissue we term organs or viscera.

Upon the preservation of this rhythm—that is to say, upon the maintenance of the normal relations among the activities of the various organs—depends the proper balance of function, the *intrinsic organic harmony*, which constitutes the health of the organism as a whole—in the case of man, the health of body and mind.

Upon the preservation of this rhythm—that is to say, upon the maintenance of the normal relations between the organism and its environment—finally depends the continuance of life.

Rest is valuable in therapeutics, because it conserves energy, saving to the organism as a whole or to a particular organ or system of organs the force that might be dissipated in action; because it lessens waste and gives opportunity for the repair of impaired tissues; because it tends to permit restoration of the disturbed rhythm of internal functions; because it places the organism in a favorable relation with its environment.

Nowhere is this more manifest than in the therapeutic relations of the heart and circulatory system. In the heart itself we have visibly and palpably illustrated the necessary alternation of repose and action. Of course, absolute rest is found nowhere in nature. All terms are relative. The sun, which is at rest in relation with the system of planets revolving about it, is in motion in relation with the so-called fixed stars, which latter are fixed only in the name they have derived from certain of their relations with earth. And so, too, the sciences which deal with the ultimate elements of matter assume the incessant motion of these in relation with each other, even though one aggregation of

restless molecules may be at rest in relation with another such aggregation.

Now, while the living heart is never at rest, absolutely speaking, yet its two opposite motions may, in relation with one another, be considered periods, respectively, of repose and action, of anabolism and catabolism. The diastole, mainly a passive state, is a period of repair in relation with the systole, which, as an active exertion of energy, is a period of breaking down of tissue. In clinical studies, as a rule, we speak of diastole and systole, simply meaning thereby the diastole and systole of the ventricles. But in studies like the present we must bear in mind that there is another diastole and another systole—namely, those of the auricles—and that the ventricular and auricular motions are not supplementary, but complementary. Except for the diastolic overlapping in the so-called period of pause, auricular diastole is synchronous not with the diastole, but with the systole of the ventricles, while auricular systole coincides in time with the diastole of the ventricles. When the blood is leaving the ventricles to enter the arteries it is at the other end of the circuit entering the auricles from the veins. When it leaves the auricles it passes directly from them into the ventricles.

During diastole of the auricles, then, the heart receives into these chambers on the right side from the systemic circulation through the venæ cavæ, and on the left side from the pulmonic circulation through the pulmonary veins, the blood, which, during systole of the auricles and coincident diastole of the ventricles, passes into the latter, and by their systole is sent out from the right ventricle through the pulmonary artery into the pulmonic circulation, and from the left ventricle through the aorta into the systemic circulation. Following this is a so-called period of pause, both auricles and ventricles being relaxed. Auricular systole then follows as before. Reflux of blood from ventricles to auricles or from arteries to ventricles is prevented by valves. For proper circulation, both auricular and ventricular diastoles and systoles must preserve normal relations with each other, with the pulmonic and general blood-pressure, and with the respiratory rhythm; while for proper maintenance of health, both pulmonic and systemic circulations must preserve normal relations with each other and with organic functions generally. These relations comprise, structurally, on the side of the heart integrity of the muscle, of its membranous cover and lining, and of the valves, and the equal capacity of the four chambers. On the side of the vessels structural integrity relates to the various components of the vessel walls (fibrous, muscular, and elastic tissues) and to the endothelial lining membranes (intrinsic integrity), as well as to the absence of any cause of obstruction by pressure or otherwise due to causes external to the vessels (extrinsic integrity). Functionally, the normal relations comprise the vigor, extent, duration, and orderly succession of the various phases of the cardiac movements, the free play of the valves, the synchronous action of right and left sides. As to the vessels, normal arterial tension is the most potent factor, while proper constitution of the blood itself is a most material circumstance. While relations remain normal, the therapeutist has no function to discharge. When from any cause normal relations become disturbed, the problem presented to the therapeutist is, first, how to avert the immediate dangers arising from such disturbance; and, secondly, how to remedy the disturbance. Both phases of the problem may coincide, and the same measure solve both; or temporary measures may have to be instituted to meet an emergency, which may afterward be withdrawn or modified as the main difficulty comes under control. In combating the main difficulty our measures may be radical—that is to say, they may aim to *remove the cause* of the trouble; or, should this be impracticable, they may aim, notwithstanding persistence of the cause, to *restore equilibrium* by artificial means.

Restoration of equilibrium—that is, of the normal balance of function which constitutes health—may be accomplished *directly or indirectly*.

Direct restoration of equilibrium implies exaltation of a depressed function or depression of an unduly exalted function to the normal level. An example of such direct restoration as accomplished by Nature is given by the illustration of spontaneous healing cited in our first lecture, the compensatory hypertrophy of the heart which frequently takes place in cases of insufficiency of the mitral valve. Here the enlargement of the ventricle and the increased force of the systole compensate for the leakage of blood which takes place through the damaged valve, and the balance of function is preserved. We imitate this natural compensation when we administer digitalis to increase the vigor of the cardiac contractions.

Indirect restoration of equilibrium implies either depression of normal functions to the level of an impaired function with which they may be correlated, or, on the other hand, elevation of normal functions to the level of an unduly exalted function with which they may be correlated. An example of such indirect restoration of equilibrium, at least temporarily, by Nature, is the arrest of hæmorrhage by syncope, where the action of the heart is depressed to the level of the impaired resisting power of the injured vessels. This is therapeutically imitated at times by the administration of aconite or the application of ice over the præcordium in cases of hæmoptysis; or, as is sometimes done by military surgeons in cases of wound through the lungs on the battle-field, by the letting of blood from an arm.

Nowhere is the therapeutic problem more complicated by the complicated relations of various functions than in the case of morbid derangements of the circulatory system, and nowhere are the results of intelligent study of the problem leading to a proper adaptation of means to end more brilliant.

In our study of the blood we saw how the scriptural phrase, "The life is in the blood," might serve to remind us of a biological truth of prime importance.

As the amœba and similar organisms live in the water, so do the cells which make up the tissues of higher forms of life live in the fluids which pass from the terminal blood-vessels into the intercellular lymph-spaces. Literally, *in* the blood is the life. As the amœba takes from the water materials for its upbuilding and discharges into the water

the waste products of its activity, so do the cells of our tissues take from the nutrient lymph the materials for their anabolism, and discharge into it the products of their catabolism. But we have already seen that the products of catabolism are dangerous to the economy; that every living thing is poisoned by the products of its own activity. As —to take analogous but not exact illustrations—carbonic acid and water, products of combustion, may be used to extinguish conflagration, and as the products of chemical decomposition interfere with the action of an electric battery, so throughout the world of life appears to rule this general law: *The end-products of an action bring that action to an end.* Thus alkalies check the activity of glands which secrete alkaline fluids, and acids restrain the secretions of acid-producing glands. Thus, in the presence of a certain amount of peptones, products of its own action, pepsin ceases to produce further change, renewing its activity when the peptones have been removed. The result of action being present, the stimulus to action is withdrawn. When hunger is satisfied, appetite ceases to be manifested. So, unless the products of the breaking down of tissue, which are the result of functional activity upon the part of cells, are withdrawn from the cells, their power for further action ceases.

It is not only "well," as the old song phrases it—it is absolutely necessary for our tissues

"to be off with the old love
Before they are on with the new."

As the new is brought by the nutrient liquor which passes out from the capillaries—that is, by the arterial or aerated blood—so the old is taken up and carried away by the lymphatics and venous radicles; that is, by the venous or carbonated blood. In this exchange of "new lamps for old" the functions of the whole elaborate system of viscera—that is to say, of heart and vessels, and lungs and blood-making organs, and digestive apparatus and eliminating organs, with their nerves and ganglia, the functions of the whole system of so-called organic life—culminate. It is for this end they have being and activity. And in this final consummation the heart plays a most important part; for upon the proper rhythmic activity of that organ depends the constant circulation which renders the exchange possible.

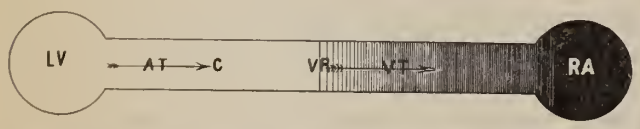
We have seen in our previous studies that a thorough knowledge of anatomy and of physiology is absolutely essential before we can intelligently apply our knowledge of the powers of the *materia medica* to the study of the treatment of the sick; that is, before we can take up the true science of therapeutics.

The facts just passed in review serve to again emphasize this truth for us in connection with the circulatory system. In all our considerations of the actions of drugs upon the heart and vessels we must bear in mind the terminal circulation. We must remember the interchange of gases, of oxygen, and carbonic acid, not only in the lungs, but also in the intercellular lymph spaces—the *internal respiration;* and the allied processes of final assimilation and initial excretion—that is, the bringing of the materials of cellular anabolism and the taking away of the products of cellular catabolism—of which it may stand as type. We must consider, then, not alone the state and action of the heart, but also of the vessels. We must consider the distribution of the blood, peripherally, ventrally, in the various organs; the relative quantities of blood in the venous and arterial systems; as well as the relation which the whole amount of blood bears to the propulsive power of the heart. We must consider the conditions which favor and oppose circulation not only in the heart itself, the main trunks, and the larger vessels, but also in the capillaries, in the lymph spaces, in the venous radicles. We must consider the conditions which favor and oppose the internal respiration, and also the pulmonary respiration. We must inquire into the conditions affecting the pulmonary circulation. We must examine the condition of the great abdominal vessels—the portal circle; and estimate the effect of our therapeutic measures upon the organs of elimination, especially the skin and the kidneys, which are so powerfully influenced by changes in blood pressure and in the tension of the vessel-walls. Other considerations, also, come into view, which, however, can be more appropriately discussed in their special relations. But, above all, we must remember that our prime object is to *restore equilibrium, to re-establish the balance of function,* for that constitutes health. And, in order that we may be able to choose proper measures by which to re-establish equilibrium, we must inform ourselves as to all the disturbing factors. Thus it is that, while so-called "polypharmacy"—the objectless throwing together of a number of drugs in one prescription—is to be unhesitatingly condemned, yet in the application of remedies to the treatment of diseases affecting the heart and circulation it is often necessary to intelligently combine agents some of whose actions are in opposition. Digitalis, for example, may in some cases of cardiac dilatation, while acting beneficially upon the heart, yet, through its action upon the vessels in unduly heightening arterial tension, tend to again disturb the equilibrium which its cardiac action tends to restore. In such cases, as has been more especially shown by Bartholow, we can, by the simultaneous administration of nitroglycerin, which relaxes the terminal vessels, modify the digitalis effect; and the therapeutic object—*restoration of the balance of function*—is successfully accomplished. This, however, will be better discussed in our next lecture, when we take up special conditions and the principles governing their management. In the time that now remains to us we must try to gain some further insight into the important relations between those two great factors in the circulation which the example just cited shows us in apparent opposition—the systolic impulse and the arterial tension. Here we must again call to mind the two fundamental laws of physics we have had such frequent occasion to cite. "Motion takes place in the direction of least resistance." "Every action has an equal and opposite reaction."

The force by which the blood-current overcomes resistance is called the blood-pressure. The great cause of blood-pressure is the systolic contraction. Pressure is greatest in the ventricles during their systole, and least in the auricles

during their diastole. Therefore these states, as we have seen, being coincident in time, the blood moves *from* the ventricles (in systole) and *toward* the auricles (then in diastole), traversing meanwhile the systemic and pulmonic vessels. These vessels afford the only route of communication between the left ventricle and right auricle on the one hand (systemic circulation), and between the right ventricle and the left auricle on the other hand (pulmonic circulation). There must be a gradual and continuous fall of pressure along these routes from terminal to terminal, in order to permit the movement of the blood, which takes place in the direction of least resistance. As pressure acts equally in all directions, the blood-pressure opposes the action of the heart in systole, and favors the action of the heart in diastole; in other words, there is, in consequence of the blood-pressure in the arterial system, a constant tendency toward reflux to the heart, which is normally prevented during systole by the higher pressure in the heart, and during diastole, so far as the ventricles are concerned, by the closure of the pulmonary and aortic valves. Thus the blood-pressure at any point represents the *possibilities of circulation* at that point. It should be higher than at the point beyond, and lower than at the point preceding. Whenever these conditions are reversed there is obstruction to circulation.

Passing over and neglecting anatomical and physiological details with which I must assume you to be familiar, we can, I think, render the subject somewhat clearer than I find it to be in the minds of most students whom I have had occasion to question, by a diagram in which we shall ignore the pulmonic circulation and separate the two terminals of the systemic circulation—the left ventricle and the right auricle—considering only the passage of blood from the former of these to the latter.



Let L. V. represent the left ventricle, whence the arterial blood flows in the direction of the arrow through A. T., the arterial trunks, C, the capillaries; and now, taking up waste products and therefore becoming venous blood, as shown by the shading, on through V. R., the venous radicles, and V. T., the venous trunks, into R. A., the right auricle. At L. V. there is positive pressure (+), at R. A. there is a slight negative pressure (—), or aspiration; consequently the current, taking the direction of least resistance, flows *from* L. V. *toward* R. A. There is a gradual and continuous fall of pressure as we proceed along the vessels, and this renders possible a regular and equable flow of blood. If the pressure at any point between L. V. and R. A. were to fall below that of R. A., the blood would tend *toward* that point from both terminals, and circulation would be correspondingly impeded. If, on the other hand, the pressure at any intermediate point should become greater than at L. V., the blood would tend *from* that point in both directions; it would raise the pressure at R. A. and it would resist the onflow from L. V., and circulation would be impeded. Any intermediate degree of alteration of pressure would have effects proportionate to its degree.

Now, so long as the caliber of the tube A. T. to V. T.—that is, of the vascular system—remains unchanged, blood-pressure depends almost exclusively upon the contraction of L. V. But should the tube contract, thus increasing resistance, or dilate, thus lessening resistance, blood-pressure would *rise at the point of contraction* and *fall at the point of dilatation* without reference, and perhaps in opposition, to the action of L. V. As the blood presses equally in all directions, it presses on the walls of the arteries and stretches them, or puts them in a state of tension. Hence *the arterial tension is the measure of the blood-pressure*, and the two terms are used interchangeably. If, by contracting the vessels, we increase arterial tension, blood-pressure is heightened. If, by dilating the vessels, we diminish arterial tension, blood-pressure is lowered. Conversely, if, by forcing more blood into the arteries, we heighten blood-pressure, arterial tension is increased; or if, by diminishing the flow of blood, we lower pressure, arterial tension is diminished. The one is the measure of the other, and they rise or fall together. Practically it is the same condition with two names depending on the side from which it is looked at.

Now let us go one step further, so that in our next lecture we may be prepared to bring all our facts to a focus. While the blood-pressure normally varies, falling regularly from L. V. to R. A., there is a certain average, or *mean pressure*, which is an important factor in the circulation. The mean pressure represents the relation between L. V. and R. A. If, for example, pressure should become too low in R. A., the blood would tend to accumulate on the venous side, unless a corresponding fall was brought about at L. V. But if there should be a fall at L. V. and not throughout the whole system, circulation would still be impeded proportionately. Therefore the *mean pressure* must also fall before equilibrium can be restored. So is it, too, in any other case of alteration at the terminals or along the course of the vessels. The *mean pressure* must rise or fall to correspond with the rise or fall at L. V. Now, this mean pressure is very largely under therapeutic control. It is governed by a special nervous mechanism—the *vaso-motor system*—which, by acting on the muscular fibers of the arteries and arterioles, and probably on the protoplasm of the capillaries, causes them to dilate or contract. Local contraction heightens, and local dilatation lowers, local blood-pressure. General contraction heightens, and general dilatation lowers, general or *mean* blood-pressure. We have many agents by which we can act locally and generally, directly and indirectly, on the vessels and on the nervous mechanism which regulates their caliber. Some of these, such as heat and cold, irritants and counter-irritants, we have already discussed. Others will be considered at our next meeting.

Change of Address.—Dr. Frank Ferguson, to No. 20 West Thirty-eighth Street.

Original Communications.

SOMNAL, A NEW HYPNOTIC.*

By W. GILMAN THOMPSON, M.D.,
VISITING PHYSICIAN TO THE NEW YORK AND PRESBYTERIAN HOSPITALS; PROFESSOR OF PHYSIOLOGY IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE.

Somnal is a new hypnotic which was introduced a year ago by Radlauer,† of Berlin. It is formed by a union of chloral, alcohol, and urethan, but the resulting compound is a complex body and not a simple mixture. Its physical characters are thus described by Dr. Frank Woodbury,‡ of Philadelphia, who administered it in several cases, in doses of from twenty to thirty minims, with very favorable result:

Physical Characters.—"Somnal is a colorless liquid, resembling chloroform in its appearance and behavior when added to cold water, in which it forms globules and refuses to mix or dissolve. When shaken with water, the mixture is milky, but quickly separates. It is soluble in hot water and alcoholic solutions, and dissolves resinous substances and fats. The odor is faint, not very penetrating or disagreeable, and resembling that of the spirits of nitrous ether, or recrystallized chloral. The taste is very pungent, and for administration it needs free dilution. It may be given with whisky or syrup of licorice. Somnal is inflammable, burning with an alcoholic flame; it does not evaporate quickly, and leaves a greasy stain upon blotting-paper. Specific gravity greater than water; reddens litmus paper slightly."

I have recently tested the physiological action and toxic effect of the drug upon animals at the Loomis Laboratory as follows:

Experiment I.—Five cubic centimetres were injected slowly into the rectum of a cat. In a minute and a half the tongue and retinal vessels became decidedly congested. The pupils were dilated and the pulse became rapid, but not very feeble. In ten minutes slight paresis of the hind legs appeared, and the animal staggered in walking. The fore legs were unaffected. Defecation ensued, which was performed with great muscular effort. When in a sitting posture there was evident vertigo, indicated by swaying of the head and body. The facial expression was dull and listless, and the animal was apparently sleepy, but was easily aroused by coaxing, when she would stand up and walk with an unsteady gait, the hind legs not being well straightened. I attributed the cat's difficulty in walking to vertigo rather than to actual loss of power, for the fore legs were not affected at all, and the hind legs were voluntarily used with good coordination in scratching her sides. In twenty minutes the cat became very quiet and sleepy. Both pulse and respiration were increased by about half the normal rate. When aroused by a call, the animal would get up and walk about with unsteady gait, but soon sought a quiet corner and dozed. In forty-five minutes she became much steadier on her feet, and, after a few more naps, appeared perfectly normal. The rectal temperature fell two tenths of a degree.

Experiment II.—Fifteen cubic centimetres of somnal were injected into the stomach of another cat through an œsophageal tube. The animal died in two minutes. The respiration ceased first, and the heart stopped half a minute later. Post mortem examination showed the liver and spleen both greatly congested and enlarged by engorgement with venous blood. The stomach was congested and irregularly contracted from the local stimulation of the drug. Peristaltic movement of the intestines and tremors of the exposed voluntary muscles lasted unusually long. The heart had stopped in diastole with the right ventricle greatly distended, as in chloral poisoning. The pupils were dilated.

Experiment III.—To a black-and-tan dog, weighing nine pounds and a half, twenty-five minims of somnal were given by hypodermic injection. There was no evidence of local irritation. After fifteen minutes no effect was noted. In twenty-five minutes there was slight vertigo, indicated by swaying of the body in walking. There were muscular tremors, especially of the hind legs. The pupils were dilated. The dog walked about wagging his tail, but seeming very restless and uneasy. When his attention was diverted he appeared better and looked brighter. There was no important change in pulse, respiration, or temperature. In thirty-five minutes the dog appeared very drowsy, but occasionally opened his eyes. In a sitting posture the body swayed to and fro and the head drooped. In fifty minutes the dog was fast asleep. In an hour and a half the dog was awakened and appeared normal in every respect.

Experiment IV.—To a large bull-dog, weighing twenty-three pounds and a half, thirty minims of somnal were given by hypodermic injections. There was no local irritation. In ten minutes he showed decided tremors of the muscles of the face and abdomen and all the extremities. There were no convulsions, merely decided twitching at irregular intervals. The animal could walk well enough, but seemed to prefer quiet. The conjunctivæ were congested and the pupils dilated. In fifteen minutes the animal appeared extremely sleepy, and it cost evident effort to awaken when aroused by noises. In half an hour the tremors had diminished, and principally affected the hind legs. In an hour and a quarter the dog was again in a perfectly normal condition.

Experiment V.—A large mongrel dog, weighing twenty pounds, was etherized, and a cannula was inserted into the right carotid artery. The cannula was connected with a mercurial manometer, and tracings of the normal arterial pressure were recorded by a kymographion. Thirty minims of somnal were injected into the abdominal wall. The subsequent tracings showed a decided increase of arterial tension occurring within the first eight minutes, followed by a gradual return to the normal within a few minutes. The influence of the respiratory curve on the blood-pressure curve became much less marked than normal. No other effects of the drug were evident and the dog recovered completely.

These experiments show that—

I. The ordinary dose of somnal (thirty minims for man) may be given by hypodermic injection to dogs without other effect than drowsiness and slight vertigo and muscular tremor.

II. A dose of one fluid drachm and a half failed to affect a cat except in the same manner as the dogs.

III. A fatal dose of half a fluid ounce stopped the respiration before the heart and caused congestion of all the abdominal viscera.

IV. The blood-pressure in the arteries of a dog is temporarily increased by somnal, soon returning to the normal.

In the past few months I have given somnal fifty-four times in doses varying from thirty minims to a drachm. It

* Read before the New York Clinical Society, October 24, 1890.

† *Zeitschrift des Apothekers-Vereins*, November, 1889.

‡ *Dietetic Gazette*, July, 1890.

was given to forty different patients, and very careful records of the effect in each case were tabulated, for which I am indebted to Dr. H. A. Griffin, house physician to the New York Hospital, and Dr. E. W. Perkins, of the house staff of the Presbyterian Hospital. So far as possible, patients were selected who were in the habit of sleeping very poorly, and not at all, unless some hypnotic was given them. Every care was taken to select only those patients who presented well-marked cases of insomnia. Cases were selected also with a view to having as great a variety as possible in the causes of the insomnia. The list includes, therefore, insomnia due to rheumatism, phthisis, bronchitis (cough), typhoid delirium, delirium tremens, sciatica, various forms of pelvic pain, neuralgias, etc.

The records comprise the diagnosis of the case, the size of the dose, the time occupied in going to sleep, the duration and character of the sleep, condition on awakening, after-effects, effect on digestion, etc. Of the fifty-four instances in which somnal was given, it produced sleep twenty-six times within fifteen minutes and forty-three times within an hour. In six cases only is it noted as having no effect at all. In a few other instances where it failed to induce sleep it was found to have a very soothing and quieting effect. Sixteen patients slept practically all night after taking half a drachm. Fifteen more slept between three and six hours, and the remainder for briefer intervals.

In most of the patients the character of the sleep was natural; in only one or two cases did it seem more profound than usual. There were no after-effects noted in any case, with one exception—that of a patient with tuberculosis, who slept seven hours and a half, after a half-drachm dose, and felt depressed on awakening. Most of the patients felt considerably refreshed, many of them decidedly so. There was no disturbance of the stomach or of digestion, with one exception, where a patient with endometritis complained of pain after taking a dose of half a drachm. Doses of forty-five minims, and even sixty minims, produced no depression of the circulation or respiration—a very different effect from that of large doses of chloral. A patient with delirium tremens became drowsy in a few minutes after taking a drachm, but soon had to be quieted by other remedies. A case of typhoid fever with active delirium, almost maniacal, was unaffected by forty minims, but was immediately quieted by hydrobromate of hyoscine. Pain or cough, if severe, was not much relieved, though a soothing effect was sometimes observed.

Conclusions.—1. The effects of somnal are much more striking and certain than those of urethane, and far less depressing than those of chloral.

2. There is no vertigo or depression after taking somnal, such as may follow the use of sulphonal.

3. The action of somnal is usually very prompt, and doses of half a drachm, disguised in a little syrup of tolu or whisky, are always well borne, easily taken, and entirely without deleterious effect.

4. The drug, in doses of a drachm, is not powerful enough to decidedly control delirium tremens, maniacal delirium, or severe pain.

5. In doses of thirty or forty minims somnal is a safe and reliable hypnotic for ordinary insomnia.

Before making the physiological experiment above described, to determine the effect of somnal upon the blood-pressure, I gave it continuously to a patient with chronic interstitial nephritis and endarteritis, with phenomenally high tension. He had been taking frequent ten-grain doses of chloral, which reduced the tension very well. Thinking that somnal might have a similarly favorable action, I gave it in frequent doses instead of the chloral, but the tension immediately returned to the high degree that existed when the patient was first seen, and remained so extremely high that I was obliged to return to the chloral with the addition of nitroglycerin.

So many of the new hypnotics have one or more objectionable features, and their continuous use results in so many new drug "habits," that it is an evident advantage to have another remedy of this class which can be used interchangeably with others if desired, and which seems to be singularly free from injurious effects and yet strong enough to act promptly and efficiently in ordinary insomnia not due to intense pain or delirium.

THE VALUE OF EXPERIMENTAL MATERIA MEDICA.*

By CHARLES H. STOWELL, M. D.,
WASHINGTON, D. C.

The materia medica of our forefathers consisted largely of a mass of empirical facts. These Bechat defined as "the shapeless mass of inexact ideas." But out of this mass evolved much that was of undoubted value. As the therapeutical art advanced, however, it was more and more clearly seen that the materia medica of the future must be based on a study by the physiological method. It was only by this physiological test that we could enter into the very secret recesses of Nature. And thus the physiological action of a drug became our ruling principle.

Without doubt the physiological method is not only vastly superior to the empirical, but is also rapidly displacing it. It is not the object of this paper to advocate a change in this particular, but rather to utter a word of caution and criticism—a word of caution lest we be too eager to accept in full the edicts of our modern scientific schools; a word of criticism lest we altogether refuse to accept the results by the empirical method. We are led, therefore, to ask the following questions: What is the value of experimental materia medica? Can we accept as a safe guide the therapeutical conclusions based upon observations made on the lower animals? Is the action of a drug the same on the well as on the sick? If the action of a drug is one thing on the lower animals and a vastly different thing on man, of what value are the extensive experiments detailed to us in our current literature and in our works of reference? And in the case of new drugs, of what value are the

* Read before the Medical Society of the District of Columbia, October 22, 1890.

conclusions derived from a study of their action on the frog, the dog, or the rabbit? Again, if drugs affect some of the lower animals differently from others, who is to decide which animal is the proper one to give us the true (?) physiological action? Then, again, if a drug does not have the same action in the various forms of disease, which disease must be chosen to give us its standard effect? In conclusion, if we are to rest fully content with the physiological method to the abandonment of the empirical, will we not be lost at sea without a rudder?.

In order to refresh our memories, let us present the following illustrations, collected from standard writers:

Chloroform.—The physiological effects of chloroform on man are well known. Yet Nunnely subjected the limbs of frogs and toads to a vapor of chloroform, and then proceeded to excise them piecemeal, without the animals betraying any signs of pain. Professor Simpson and Mr. Nunnely easily produced local anæsthesia on fish, frogs, insects, etc. Now, while it is true that many logical conclusions have been drawn from experiments on the frog, yet we would hardly be justified in beginning an amputation of a finger simply after immersing it in this anæsthetic.

Nux Vomica.—The experiments of Klapp prove that in the cat and rabbit strychnine slows the pulse. Bartholow says that in man the heart's action is accelerated. He thinks this apparent contradiction, however, may be explained by the dose employed. During the spasms of dogs the animals appear insensible to all impressions. They could be cut with knives without exciting signs of pain, but "in man the mind remains clear and unaffected; it is probable that little pain is experienced." In the case of the dog, either the susceptibility of the animal is primarily affected, or the pain is so severe that the extreme pain of cutting is not noticed.

Opium.—We are told that the poppy is a favorite food of the rabbit. He will actually thrive and get fat on such a diet. Three grains of the acetate of morphine have been given to this little animal with no effect. Based upon these experiments, it would seem safe to assume that this is quite a harmless weed, and that its active principle—morphine—is quite inert. Large doses of opium given to dogs appear to affect the motory powers, but do not produce coma. The purely instinctive emotions of the lower animals remain unaffected.

Quinine.—Stillé says that this drug, given to dogs, deranges, enfeebles, and finally extinguishes nervous action. Thirty grains given to a dog caused death in twenty-four hours. Dr. C. W. Brown reports that two grains placed on the tongue of a full-grown, healthy cat caused a violent convulsion within two minutes. The conclusion from this would be that quinine is a virulent poison, and should be used more cautiously than opium.

Quassia.—If an infusion of quassia is placed within the reach of flies, they will drink it, get benumbed, and act as if dead, but will finally recover. A new anæsthetic, sure enough! Rabbits are killed by concentrated preparations of the drug. Two grains of the extract of quassia applied to fresh wounds have caused the death of rabbits in from thirty to seventy-two hours. A mangy dog, washed in a decoction of quassia, lost the use of his hind limbs for seven hours.

Turpentine.—Two drachms of the oil of turpentine destroyed the life of a dog in three minutes, with signs of great suffering. Half an ounce killed a rabbit in sixty hours. In man, Bartholow says, the only fatal cases have been in children. He says from four to six ounces have been taken by adults. A child only fourteen months old took four ounces and yet recovered. Yet experimental materia medica would place this among the most dangerous of drugs.

Bismuth.—Orfila states in his *Toxicologie* that the subnitrate and nitrate of bismuth given to animals caused vomiting, depression, debility, dyspnœa, and death. The gastric mucous membrane was inflamed, softened, and ulcerated. Meyer, of Bonn, verified these observations. Yet how general is the use of this drug! As many as six drachms a day have been given to children only two months old.

Conium.—It is stated that the sheep and goat can eat conium without injury. Rabbits and horses have no mischief resulting from its use. One horse ate three pounds and a half without inconvenience. Cows may eat it freely also.

Arsenic.—This powerful drug may be administered in very large doses to horses without toxic effects. Birds will withstand a dose sufficient to destroy an amphibious animal of equal size.

Potassium Iodide.—De Vergine gave a dog two drachms of the iodide of potassium in an ounce of water, and the animal died on the third day. Magendie took two drachms of the tincture, equal to ten grains of iodine, without injury. An infant three years old took three drachms of the tincture at one time, and no bad effects followed.

Cod-liver Oil.—Experiments have shown that many of the lower animals do not thrive well when given this food. If pigs are given more than from one to two ounces a day, or sheep more than an ounce, or oxen more than from three to nine ounces, the oil invariably disagrees with them.

Alum.—We are told that there is not a fatal case on record from the use of alum. Yet two drachms of it in solution were fatal to a rabbit, as reported by Mitscherlich.

Jalap, *colocynth*, and *gamboge* are almost inert when given to the horse.

Emetics.—Emetics given to rabbits fail to produce any results, but if given to dogs the results are most marked, because the former never vomit, while the latter do so easily.

Ergot.—In discussing the physiological effects of this drug, Bartholow notes the following: "An enormous rise in the blood-pressure has been stated to occur by Eberty, Köhler, and H. C. Wood, and their opinion was based on kymographic observations. Holmes, Herrmann, and Wernich, on the other hand, maintain that the blood-pressure is actually reduced." From this mass of contradictory evidence how are we to glean the true from the false?

From a study of these well-known drugs it is evident that their physiological effect on the lower animals is different from that on man. In this connection we would call attention to a recent article by Dr. Huchard on The Physi-

ological and Therapeutical Action of Drugs, read before the *Société de thérapeutique*, in which he calls attention to the marked differences in the action of some drugs in various forms of disease. He says that the action of some drugs is not the same in the well as in the sick. He states that quinine will lower the temperature in typhoid fever, but will not do so in erysipelas. He draws the conclusion from his observations that "it is not safe to make sweeping therapeutic deductions from observations of the physiological action of drugs." Concisely stated, he asserts that "physiology should not enslave medicine." In this connection would we recall the investigations of Professor Lichtheim on *resorcin*. He says he noticed the greatest difference in the power of resorcin to lower the temperature in the different fevers. All practitioners are aware of the power of the system to resist immense doses of opium in cases of peritonitis.

Now, if what has been said be accepted, two things must logically follow: First, the physiological action of any drug on the lower animals must not be accepted as its physiological action on man until fully corroborated by direct experiment on him. Second, direct observation of the action of a drug at the bedside must be an essential part of the foundation of our therapeutics. It follows, therefore, that the value of experimental materia medica is limited. Still further it follows that the medical student of the future must learn his therapeutics in the dispensary and hospital.

Deductions emanating from experimental laboratories should not be accepted until repeated observations on the human body, in health and disease, had fully corroborated the same. The physiological method is certainly vastly superior to the empirical, but it will ultimately lead us into confusion and chaos unless it goes hand in hand with every-day experience and observation.

PULMONARY PHTHISIS

TREATED BY INOCULATION WITH ANIMAL VIRUS.

By J. HILGARD TYNDALE, M. D.

This paper is intended as a preliminary report. The forthcoming report of Professor Koch's experiments is my excuse for giving my results to the medical world at this time. It will save me from being looked upon as a plagiarist.

For the past four months I have been treating a series of six cases of pulmonary consumption by *inoculation with animal virus*. The cases selected were all afflicted with actively destructive suppurative processes of the lung, and in all the presence of the *Bacillus tuberculosis* was demonstrated.

For the sake of brevity, let me present the method under four headings:

1. The necessity of exact and localized diagnosis. No case of mere connective-tissue processes, general or localized cirrhosis of the lung tissue, or binding down of the lung by pleuritic adhesions. The cases to be selected are active cavities and infiltrations, with suppurative expectoration and the presence of the bacillus. In all of my cases the temperature was persistently high. All but one had suffered great loss of flesh and were very anæmic.

2. The substance used for inoculation is the *pure vaccine lymph* obtained from the cow. This is not the time and place to give the details of the technique of inoculation, which is tedious, and requires an exact attention to detail.

3. Blood and fat formation, according to the requirements of each particular case. This line of treatment should be inaugurated from the beginning, or at least shortly after the first inoculation.

4. Lung gymnastics. This feature of my mode of treatment is of equal importance with the others and should never be neglected. It consists of deep inspirations at stated intervals.

Follow the cases:

Case I.—Marcus F., aged thirty, shoemaker; mother died of phthisis at the age of thirty-six. Large cavity at right apex. Infiltration with dullness down to upper border of fourth rib. Temperature, 102°. No appetite. Great weakness. Had three hæmorrhages within six weeks preceding inoculation. Sputa not very copious, containing bacilli and pus corpuscles. Inoculated twice. Present condition (existing since October 9th): Strength and appetite excellent. No further hæmorrhages. No bacilli. Occasional dry cough, but no expectoration. Cavity about half the original size. Vesicular murmur in place of infiltration. Has resumed work.

Case II.—Joseph B., aged thirty-two, porter. Sick for two years. Temperature, 99°. General nutrition good. Cavity at left apex. Pleuritic adhesions along inner edge of right scapula. Moderate expectoration, with sparse bacilli. Inoculated four times. Present condition: Normal strength and appetite. Last examination of sputa revealed a few bacilli (October 14th), since which time patient claims to be unable to cough up material for examination. No moist râles, but cavernous respiration only heard over cavity. Pleuritic adhesions disappeared.

Case III.—Marcus F., aged thirty-four, barber. Sick for five years. Great emaciation. Temperature, 101°. Very weak and no appetite. Moderate-sized cavity under right clavicle, with dullness to interspace between second and third rib. Infiltration left apex to lower border of third rib. Rapid and feeble heart's action. Copious expectoration; bacilli in great number. Inoculated three times. Present condition: Appetite normal and bodily strength very much improved. Emaciation unchanged. Temperature, 98°. Professes to be unable to furnish sputa since second inoculation, as his cough is a dry one. Cavity contracted and empty; friction râles in circumference. Infiltration left and right sides has disappeared, but respiration still feeble on right side, with occasional dry crackles.

Case IV.—George D., aged thirty-six, satchel-maker. Sick eight months. Great emaciation and weakness, and very anæmic. No appetite. Copious night sweats. Temperature, 103°. Feeble and rapid heart's action. Infiltration of left apex to about lower edge of third rib; infiltration of right apex to fourth rib. Expectoration moderate. The first microscopical examination revealed pus corpuscles and broken-down epithelium, but no bacilli. The second examination showed bacilli "few in number." Inoculated four times. Three weeks ago was suddenly seized with pleuritic stitches on left side, followed by full-fledged serous effusion into the pleura. This disappeared six days after the fourth inoculation and gave way to vesicular murmur. Present condition: Good appetite and increasing

strength; no notable gain in flesh, and paleness of skin, notably of the face. Temperature, 98° for the last ten days. Sputa: Pus corpuscles, no bacilli. Says quantity of expectoration is very much diminished. Vesicular murmur in place of infiltration right apex, and, as stated above, total disappearance of pleuritic effusion. Broncho-vesicular breathing, with sparse râles at left apex.

Case V.—Max G., aged thirty-six, peddler. Sick four months. Dr. Fishman, of Rivington Street, was kind enough to turn this case over to me. Very feeble; great emaciation and anæmia, and total loss of appetite. Temperature, 103°. Two medium-sized cavities in upper lobe of left lung, with surrounding infiltration. Infiltration of right lung to lower border of second rib. Feeble respiratory murmur over the posterior portion of the whole left lung. Copious sputa, with abundant bacilli. Inoculated four times. Present condition: Strength and appetite very much improved. Temperature, 99°. Microscopical examination (October 31st): "Bacilli not very numerous. Broken-down pus corpuscles." Expectoration diminished by about one half; muco-purulent. Cavities of left lung unchanged. Normal vesicular breathing over the whole of posterior portion of left lung. Exaggerated vesicular murmur at right apex where infiltration used to be. I have my doubts whether in this case the remaining lung surface will suffice for a final cure.

Case VI.—Johanna F., aged twenty-nine, widow. Family history excellent. Her husband died of phthisis about a year ago. Shortly after, she was seized with a cough and has been declining ever since. Moderate emaciation, but very weak and extraordinarily pale. Temperature, 102°. Expectoration copious and purulent. Microscopical report: "Could never get a field which showed more than two bacilli." Infiltration, with dullness and moist râles of both apices, with total absence of vesicular murmur. Inoculated three times. Present condition: Very much increased strength. Better color in her face; temperature, 100°. Expectoration muco-purulent. "Bacilli very few in number." Dullness gone over both apices. Feeble respiratory murmur over left apex. Broncho-vesicular over right apex.

My thanks are due to Dr. David Goldstein, 109 St. Mark's Place, for careful and frequent examination of the sputa. I am also much indebted to the gentlemen in charge of the vaccination department of the Board of Health, and to Dr. William C. Cutler, of Chelsea, Mass., for aiding me in obtaining virus of excellent quality and sufficient quantity.

My original intention was to allow six months to pass after the final inoculation of each patient before presenting them to the profession. Professor Koch's method will, I trust, lead to success, and it is more than possible that animal virus other than that of cow-pox will accomplish the same object. The chances are that therapeutical successes may from time to time be hatched outside of a laboratory.

In conclusion, I would request my colleagues to draw no final conclusions from what I have done thus far. At present I merely desire to put myself on record, and am not looking for cheap notoriety.

48 East Third Street.

The Macon (Georgia) Medical Society.—On the 18th inst., officers were elected as follows: President, Dr. R. O. Cotter; vice-president, Dr. H. J. Williams; secretary and treasurer, Dr. H. P. Derry; corresponding secretary, Dr. H. McHatton; reporter, Dr. W. A. O'Daniel; librarian, W. F. Holt.

THOUGHTS AND OBSERVATIONS AT "HEALTH RESORTS."

By JOSEPH WILLIAM STICKLER, M. D.,
HOT SPRINGS, N. C.

Many invalids may be found on mountain-tops and in the valleys who ought to go home and remain there. The great majority of invalids who are now in their own homes should stay there. Money can not buy or friends provide home comforts in hotels or boarding-houses. Big fees or little do not prevent "drummers" coming and going at various and unseasonable hours, and slamming doors, all of which is not conducive to sleep or helpful to persons who go from home to secure undisturbed slumber.

Patients who can not sit upon the piazza at home without risk after sundown may sometimes be seen knee-deep in a trout-stream, or perched upon a log or cold rock in the damp woods watching for deer, immediately after reaching the "health resort." This is not the best and quickest road to health.

Dancing in a hot and crowded parlor or ball-room till 11 or 12 o'clock in the evening, with an occasional walk or flirtation on the piazza for the sake of getting "cocled off," does not appear to be a satisfactory method of treatment for phthisical patients, or persons whose throats and lungs are weak.

The man or woman who goes to the mountains for fresh air as a remedial agent and sits all day in a hotel may as well go home on the first "limited express," unless the individual is to be satisfied with minimum instead of maximum benefit.

The invalid who stays at a health resort just long enough to get rid of troublesome symptoms, and then goes back to business or home duties and responsibilities, very often goes home to die.

Damp sheets and a strong draught do not, as a rule, tend to re-establish a normal condition of body.

People who occupy rooms over foul-smelling water-closets and on the side of the hotel where the sun never shines do not seem to get well so quickly as those who live on the sunny side and away from cesspool infection.

Residence in a fine hotel in a malarial district does not cure malarial disease. A short stay in an elevated region which is non-malarial will often "develop" latent malarial poisoning. This is also true of some *low* non-malarious districts. Don't leave either place just because of the occurrence of a chill.

When an invalid finds a health resort which furnishes what he needs he should stay there till he becomes strong and well.

Every man, woman, and child who has phthisis in its primary stage should at once go to the best climate this country furnishes.

The Society for the Relief of Widows and Orphans of Medical Men.—At the recent annual meeting, officers were elected as follows: President, Dr. Henry Tuck; vice-presidents, Dr. Elsworth Eliot, Dr. J. J. Milhau, and Dr. Everett Herrick; treasurer, Dr. J. H. Hinton; managers, Dr. J. W. Warner, Dr. W. T. White, Dr. A. F. Currier, Dr. O. D. Pomeroy, Dr. Willard Parker, Dr. J. D. Bryant, Dr. G. T. Jackson, and (to serve one year, to fill a vacancy) Dr. A. R. Matheson.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, NOVEMBER 29, 1890.

THE RENAISSANCE IN THERAPEUTICS.

In therapeutic art and practice great changes have taken place during the past fifty years. Certain methods have been so transformed that the art seems almost new. Others have been guided to new ends, and the scope of many is much enlarged. In and about 1840 medical poverty seemed almost to equal that of Scott's country doctor, with his two simples of "calamy" and "laudamy."

Interesting indeed is Dr. John Kent Spender's paper, in the *Practitioner* for October, on the therapeutic revival. Pathology, he says, was in great fashion between 1845 and 1870, and diagnosis was worshiped and deified. Medical energy ran in the direction of necropsies and microscopes. Post-mortems that showed a doctor to be right were more esteemed than a cure that proved him wrong. Morbid anatomy was a passport to fame. But afterward a more human philosophy altered the current of professional thought, and Dr. Latham declared that the treatment of a disease was a part of its pathology. Sir Thomas Watson chided the profession for vagueness and want of earnestness in the use of drugs. Nowadays we employ our therapeutic possessions as if we trusted them, and lean upon the rock of physiological experiment and observation. And this renaissance in therapeutics has made the medical profession fellows in sympathy and work, bringing liberty and fraternity, and giving prominence to the fact that all are equal who have equal knowledge and experience.

The *London Pharmacopœia* of 1824, the official guide to pharmacy and the art of prescribing, was hidden from vulgar scrutiny by the Latin tongue. And so one G. F. Collier, M. D., in a fit of audacity for which there was no precedent, wrote a translation, with notes and criticisms. This gave mortal offense to the Royal College of Physicians, who threatened to treat it as an illegal publication. Publisher and printers were intimidated, and the latter refused to go on without a guarantee of indemnity. The book was published at last, however, and it is not recorded whether G. F. Collier was burned or imprisoned, or whether he retired into decent obscurity.

The last edition of the *Pharmacopœia* in Latin was published in 1851. Associated with this epoch are the names of three distinguished men—Pereira, Royle, and Copland, prophets and teachers, all like each other in physical bulk and elephantine fiber. Pereira's story begins before the flood, his researches going into all lands and all philosophies. Royle knew all the therapeutic botany of India, and reveled in the flora of the Himalayas. Copland enjoyed a high reputation, and had a great London practice between 1830 and 1850. These three giants died, and others entered into their labors. The old manners softened. The home rule of separate pharmacopœias for England, Scotland, and Ireland was voted an absurd bondage, and in 1864 the *British Pharmacopœia* (in the vulgar tongue) was published. Every one found fault with it. It was called almost a failure. In 1867 another edition, with earlier errors left out, became the basis of the authorized version of 1885, the convenience of which is everywhere recognized.

An urgent problem, thinks Dr. Spender, is that of how to teach the clinical application of therapeutic science; that is, what amount of the grammar of the language should be learned before attempting to speak it. The art of prescribing is supposed to come by nature. In reality, ignorance of its methods and rules is keenly felt by many. A work of art should have consistency and integrity. And these are the special qualifications of a prescription, which ought to be a finished product of skill and experience.

The renaissance in therapeutics exhibits special skill in the analgesic group of medicines. In the dawn of some severe inflammations, notably those of the eye, morphine in doses of one twelfth of a grain every hour quiets the storm and the sympathetic tumult. When detected by the expert observer, it is stated that the initial stage of acute glaucoma has been checked by this plan. When pain is only a subordinate symptom of inflammation, like many others, tartar emetic is full of power. Take, for instance, inflammation of the whole breast after childbirth. Administer fifteen minims of wine of antimony—one sixteenth of a grain—in water punctually every hour for sixteen or twenty hours. Everything must give way to it, even sleep itself. Every hour the trouble recedes. Milk and egg may be allowed in moderation, and no other diet. Alcohol is poison. On the next day every classic symptom of inflammation will have vanished. This method will also control the acute efflorescence of psoriasis. To-day the law that small doses and large doses of the same drug exercise quite a different effect is distinctly understood. A combination of one twenty-fourth of a grain of morphine and three minims of castor oil, taken every half hour for six or seven times, may stop acute choleraic diarrhœa in a most effective manner. Medicines of a similar tendency may economize each other when given at the same time, the drawbacks of each being lessened and the efficacy of the total product increased; for example, those of a bromide and chloral.

The renaissance is glad to drop traditional baggage, the useless material that drags down the medical car. Drugs that do no good are not now prescribed. Excess of caution in dosage is the cause of many therapeutic failures. We must guide the treasures of the pharmacopœia as powerful machines that can be made to act with the finest delicacy. True courage is never afraid of power. Systematic study of the pharmacopœia would reveal riches little suspected and restorative forces of priceless worth. "Medicine is an art founded on many sciences," says Sir Dyce Duckworth, "and a great physician is a great artist." The revival in therapeutics is the birth of larger art in medicine.

FAITH-HEALING UNSUITABLE FOR AFRICAN FEVER.

Some peculiarly painful cases of loss of life through "faith-healing" have been recently brought to light. One of these cases has been the occasion of ministerial correspondence between Great Britain and Mr. Secretary Blaine, dealing with a report from the colonial surgeon, Dr. Palmer Ross, of Freetown, Western Africa. This report shows that three deaths have taken place in a band of nine young missionaries from our own Western States. These deaths took place by fever soon after the arrival of the party at their African station. Under the guidance of their leader, an ardent believer in divine healing, the sick, whether their cases were grave or mild, were allowed to go untreated by medical means; and, in the opinion of Surgeon Ross, the febrile cases began to assume an unnecessarily virulent type which endangered the whole community, and which impelled him to order officially the adoption of sanitary measures, such as isolation, disinfection, and a speedy burial of the dead. Others of the missionaries also took the fever, but they submitted to treatment, some willingly, but others under protest. Surgeon Ross then declared his intention to report the matter to the Governor and to advise that all the survivors be sent back to America, on the ground that a tropical climate was not suited to those who trusted alone to faith-healing and ignored the means placed by Providence at their disposal for the relief of suffering humanity, and that such a line of conduct was a danger to the community at large.

A late issue of a missionary journal, called the *Regions Beyond*, although very friendly to this unfortunate party in Africa, takes special care to point out the error made by them in rejecting medical treatment, and says: "These deaths took place in July, and to us it is an additional pain to know that, humanly speaking, these lives need not have been lost, but might have been usefully spent in Gospel service in Africa. Unfortunately, in passing through New York, on their way out, they came under the influence of one who teaches what is called faith-healing. From him they received the sadly erroneous doctrine that, though God has given us medicines and the skill to use them, it is contrary to his will we should do so. It is inexpressibly sad that these devoted young lives should thus needlessly have been thrown away at the bidding of a false theory. Very solemn and terrible is the responsibility of the teachers of this theory when they urge African missionaries to dispense with quinine and other antidotes to deadly fever." Among the other members of the party who also suffered from fever, but who received the usual medical treatment, there were no deaths reported.

MINOR PARAGRAPHS.

THE HYPNOTIC EFFICIENCY OF PARALDEHYDE.

Paraldehyde is represented as being the sheet anchor, among the hypnotics, in the neurological clinic at Dorpat. Dr. H. Dehio is quoted by the *British Medical Journal* as saying that that drug has been his favorite for some time, and still retains its position as the most reliable sleep-producer—superior to hypnone, methylal, chloralamide, amylene hydrate, urethane, sulphonal, and hydrochloride of hyoscine. Paraldehyde has been given by Dr. Dehio in many severe cases, the initial dose commonly being 75 to 90 minims, which was followed by another dose of 45 to 60 minims; this was found sufficient in most of the cases to give a good night's sleep. As a rule, the drug acted well, but sometimes only slight sleep followed, while at other times tolerance was too soon established: but these occasional disadvantages were more than counterbalanced by the fact that the drug, even in large doses, did not influence the heart and respiration. It may upset the organs of digestion, causing diarrhœa. The medicine must be pure beyond peradventure, and should not redden litmus paper; and it should be kept in the dark and in tightly stoppered bottles. If this is not done, it will soon become acid. The prolonged use of paraldehyde is followed by the following chain of symptoms: Loss of appetite, gray coloration of the skin of the face, dryness of the surface, and loss of weight; at the same time the drug loses its power to produce sleep. These symptoms pass off on the discontinuance of its use. Headache and depression are not among the after-consequences of this remedy, whereas amylene hydrate has those effects, but it does not interfere with the digestive apparatus to the same extent as paraldehyde does. In severe cases of motor disturbance, such as occurs in delirium tremens and mania, paraldehyde, along with six others of the hypnotics mentioned above, are practically useless; in these cases Dehio has found the hydrochloride of hyoscine, in $\frac{1}{70}$-grain doses, to be the most reliable hypnotic in such cases.

SCIENTIFIC PROPHYLAXIS.

An article in the *University Medical Magazine* for November, upon the subject of ptomaines, admits these chemical products of bacterial growth as potent factors toward the fatal issue in certain forms of disease. That such chemical compounds are formed has been pretty conclusively demonstrated by the work of Brieger and others. It is shown that these ptomaines are of the character of amines. With the cholera-infantum germ, in addition to the ptomaine proper, there is also an albuminoid body formed by the growth of the germ which is very poisonous and is probably an intermediate stage before the final development of the ptomaine. Immunity from anthrax, in guinea-pigs, has been obtained by inoculating them with albumose resulting from sterilized cultures of the anthrax germ. In the *Medical News* for September 6th and October 4th Schweinitz describes the ptomaines and albumose which he has obtained from hog-cholera culture liquids. The culture liquid used was a peptonized beef infusion. He succeeded in isolating small quantities of two old ptomaines and one new one to which he ascribed the formula $C_{14}H_{36}N_2$. He suggests the names sucholotoxine for the ptomaine and sucholoalbumin for the albumose obtained from the growth of the hog-cholera bacillus. This ptomaine, together with the albumose, seemed to be the potent poison in hog cholera. He also cites a number of experiments on the guinea-pig with the isolated compounds, in which the animals were rendered proof against the disease. This line of research is only in its infancy, but it is within the range of probability that a certain class of diseases may eventually be kept in abeyance by scientific prophylaxis.

EPITHELIOMA ADAMANTINUM.

In the *Wiener klinische Wochenschrift* for October, Dr. Derujinsky, of Moscow, describes this form of dental tumor, the occurrence of which is somewhat rare. The varieties of dental tumors previously reported have been of the colloid form, the

result of degeneration in the cell elements. There is no doubt, he says, that these growths derive their origin from epithelial remains, and that one of the evidences of such remains being present is the occasional development of supernumerary teeth and the growth of new teeth late in life. From careful examination of the literature on the subject, the author, though unable to find another case reported having similar microscopical structure, concludes that dental tumors are probably all of a common origin. The growth in the case under consideration proceeded directly from the alveolar process of the maxilla. Careful microscopical examination of the tumor showed the structure to be almost identical with that of the normal enamel of the teeth. Cohnheim's theory was that all dental tumors sprang from embryological germ tissues. The author is of the opinion that the case belonged to this class, and that trauma or some irritation of the maxilla or alveolar process had set up chronic inflammation, producing proliferation of cells, and resulting finally in the development of the enamel structure described. The tumor was non-malignant but recurrent, its reappearance being probably due, he thought, to some of the growth remaining after the first operation, as dental tumors are for the most part benign.

BONE GRAFTING.

Mr. A. G. Miller, in the *Lancet* for September 20th, reports the history of a case in which he used decalcified-bone chips successfully to fill up a large cavity in the head of the tibia. A piece of the rib of an ox was used, being first scraped and then decalcified in a weak solution of hydrochloric acid. After cleansing by pressure, it was placed for forty-eight hours in a carbolic-acid solution, one to twenty, then removed, and cut into small pieces. During the scraping out of the cavity in the knee, preparatory to the grafting, a number of small pieces of bone were removed. These were placed in a solution of boric acid for use later in the operation. The cavity was then stuffed with the decalcified-bone shavings, the pieces of fresh bone being added last. The cavity thus filled was about two inches in diameter. Granulation and healing took place rapidly; the only pieces of bone that became necrosed were from the patient's own body. The author is convinced, from his observation of this case, that the healing of large bone cavities, the result of injury or disease, is greatly facilitated by stuffing them with decalcified-bone chips, that these are superior to fresh bone, and that fresh bone not only is of no use, but actually hinders the process of granulation.

THE ORTHOPÆDIC SECTION OF THE TENTH INTERNATIONAL MEDICAL CONGRESS.

The institution of this section may fairly be said to have been due to the efforts of our countrymen. It is pleasant to see the fact frankly recognized in Europe. In a report of the proceedings, by Dr. Kirmisson, published in the November number of the *Revue d'orthopédie*, the credit of the initiative is given to Dr. Newton M. Shaffer, of New York, who, as well as Dr. Bradford, of Boston, became one of the presiding officers of the section. The *Centralblatt für orthopädische Chirurgie und Mechanik*, in an extra supplement, expresses itself to much the same purpose.

THE HARVARD MEDICAL SCHOOL.

The new laboratory of this institution is approaching completion. It stands on the easterly side of the main building, and is sixty feet in length and three stories in height. The basement contains the rooms for animals and apparatus. The animal rooms are unusually well lighted and ventilated. The ground-floor is to accommodate the bacteriological department, with large and small rooms for the instructor and special workers, provision being made for thermostats, sterilizers, a library, chemical and other glass ware, closets for clothing, etc. The two upper stories will be devoted to pathological work and photography. The old laboratory rooms in the main building will be made over for the use of the undergraduates.

THE CARE OF THE INSANE IN THE STATE OF NEW YORK.

The recent sad incident of the murder of Dr. Lloyd by an escaped lunatic is, we presume, at the bottom of that one of a number of new orders lately issued by the State Commission in Lunacy which states that no insane patient in the custody of an institution must be allowed to go out on parole who, in the medical superintendent's judgment, is dangerous to himself or to others; that no parole shall be granted for a period longer than thirty days; and that, on the escape of a patient, prompt and vigorous measures must be taken to secure his return. Another order is intended to insure to insane persons comparatively unrestricted correspondence with their friends and wholly unrestricted correspondence with State and court officers.

THE TETRAHYDRONAPHTHYLAMINES.

Dr. R. Stern, in the *Archiv für pathologische Anatomie und Physiologie und für klinische Medicin*, gives an account of some recent experiments made on animals with the tetrahydronaphthylamines. The preparation used was an aqueous solution administered hypodermically. An increase in temperature resulted in an hour, with dilatation of the pupil and general symptoms of poisoning. There was an increase in the quantity of urine voided, and in its nitrogenous and phosphatic constituents, the poison reaching its maximum effect on the second day, when the symptoms gradually subsided. The observer concluded that the changes in the urine were not those common to high temperature, but were consequent upon the specific poisonous action of the drug.

TANNIC ACID AS AN INTESTINAL ANTISEPTIC REMEDY.

Professor Cantani has written, in the *Wiener medizinische Blätter*, of his therapeutical trials of tannic acid in intestinal diseases. He has found it, in $\frac{1}{3}$-, $\frac{1}{2}$-, or even 1-per-cent. solutions, acting a useful part as an antiseptic, as it hinders the vegetative activity of the microbes and renders innocuous many of the poisonous ptomaines. In diarrhœa and dysentery, therefore, tannic acid becomes an important disinfectant as well as astringent remedy. Mosler also reports that this drug is very beneficial in typhoid fever, particularly for removing the symptoms of meteorism and diarrhœa. Antiseptic solutions are best introduced by enteroclysis, the fluid thus administered having been proved, by the subsequent vomiting of some of it, to reach not only the whole length of the intestines, but even to the stomach.

ITEMS, ETC.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 16 to November 22, 1890:*

Moseley, Edward B., Captain and Assistant Surgeon, is granted leave of absence for one month. S. O. 100, Department of Texas, November 17, 1890.

Burton, Henry G., Captain and Assistant Surgeon, is, by direction of the Acting Secretary of War, granted leave of absence for six months on surgeon's certificate of disability, with permission to go beyond sea. Par. 9, S. O. 269, Headquarters of the Army, A. G. O., November 17, 1890.

Phillips, John L., Captain and Assistant Surgeon, is, by direction of

the Acting Secretary of War, relieved from further duty at Fort Crawford, Colorado, to take effect on his relinquishing the unexpired portion of his present leave of absence, and will report in person to the commanding officer at Camp Guthrie, Oklahoma Territory, for duty at that station, reporting by letter to the commanding general, Department of the Missouri. Par. 7, S. O. 269, A. G. O., Washington, November 17, 1890.

JOHNSON, HENRY, Captain and Medical Storekeeper, is, by direction of the Acting Secretary of War, granted leave of absence from January 1 to March 24, 1891, inclusive, with permission to go beyond sea. Par. 18, S. O. 268, A. G. O., Washington, November 15, 1890.

GANDY, CHARLES M., Captain and Assistant Surgeon, Fort Clark, Texas, is, by direction of the Acting Secretary of War, granted leave of absence for three months. Par. 10, S. O. 266, Headquarters of the Army, A. G. O., November 13, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 22, 1890:*

AYERS, J. G., Surgeon. Ordered to the U. S. Receiving-ship Wabash.

EVANS, SHELDON GUTHRIE, commissioned an assistant surgeon in the U. S. Navy.

BATES, N. L., Medical Director. Ordered as president of Naval Medical Examining Board at Mare Island, Cal.

MOORE, A. M., Surgeon. Ordered as member of Naval Medical Examining Board at Mare Island, Cal.

Society Meetings for the Coming Week:

MONDAY, *December 1st:* New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

TUESDAY, *December 2d:* New York Obstetrical Society (private); New York Neurological Society; Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburgh Medical Association; Medical Societies of the Counties of Herkimer (semi-annual—Herkimer) and Saratoga (Ballston Spa), N. Y.; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association; Baltimore Academy of Medicine.

WEDNESDAY, *December 3d:* Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, *December 4th:* New York Academy of Medicine; Metropolitan Medical Society (private); Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, *December 5th:* Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, *December 6th:* Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Special Articles.

THE OPENING RECEPTION IN THE ACADEMY OF MEDICINE'S NEW BUILDING.

(*Concluded from page 582.*)

The Influence of Scientific Associations upon Great Cities was to have been the subject of remarks by Mr. D. WILLIS JAMES. The president read a letter of regret from Mr. James, who said: Very highly I appreciate the honor of the invitation to speak on the important occasion of the opening of the new and beautiful home of the Academy of Medicine of New York. It is a serious and great regret that I am prevented from being present. As a citizen of New York, greatly interested in her welfare, progress, and fame, I feel impressed with the vast importance to the city of such an institution as the Academy of Medicine as a center of most important scientific investigations, and I desire to join in the heartiest congratulations to you, sir, as president of the Academy, and to all the members, on the completion of the great work in which you have labored so faithfully. New York can not learn too soon the fact that a great imperial city can not be built upon material prosperity alone. The foundations must be deeper, broader, and more enduring. Years ago in the city of Würtzburg I was deeply impressed by the fact that the magnificent palace, begun centuries ago as a home for regal magnificence, luxury, and display, was going to ruin and was shrouded in gloom, while the hospital, started at the same time, to be of service to the wretched and suffering, was, after the lapse of centuries, doing its beneficent and holy work, out of which had sprung a medical college, the fame of its distinguished professors drawing crowds to the city. If New York is to be the great imperial city of the future we must see to it now that we plant and foster, not only churches, and galleries, and parks, but also great universities, largely endowed, and, as the most important parts of these universities, medical colleges magnificently and munificently endowed, so that they shall have every possible facility for accomplishing the best work. The beginning has been made in the endowment of the Vanderbilt clinic and in the founding, by an unknown but wise donor, of the laboratory which it was wisely required should bear the name that has added so much luster to this city—a name honored and beloved by every member of this Academy.

But far more must be done and done promptly. Look at the magnificent work the medical profession has done and is doing for suffering humanity, stirred as our enthusiasm is by the discoveries of such men as Professor Koch, of Berlin, with their promise of lasting benefit to humanity, let us, as citizens of New York, see to it that in our midst the means are ample and promptly supplied for the most complete scientific research in all departments of learning. Let this be especially so in medical sciences, and let us do promptly for New York what Johns Hopkins has done for our sister city of Baltimore.

Remarks of Dr. S. Weir Mitchell, of Philadelphia.—Dr. MITCHELL, having been introduced by the president, said: Such an introduction will, I am afraid, convey the impression that I am prepared to give you a poem, a novel, or a dose of medicine equally well. A few things have been suggested to my mind from what I have heard to-night. I may call myself one of the fellows who come from the immediate neighborhood. I am an honorary fellow and therefore not entirely a stranger, but share in the congratulations of my fellow-fellows of this Academy. How much delight it gives me to see what has been done for our profession in this palace of medicine to-night! I was reminded by some of the speakers of what I saw years ago when I visited the French Academy. I desired to find a certain book, but was unable to do so; the books were without a catalogue. Without this a library is of no more use than a man without a memory. When I inquired why this condition of things existed I was told that they were waiting for the Government to do something in the matter. You know how long we should have to wait for our Government to do anything for us. We do things a little differently in this country, and the result is before us to-night. I am often struck with the frequency with which the term "our profession" is in our mouths, and it is a phrase which sometimes provokes a smile. It should be con-

sidered rather a great guild than a profession, and this guild a great and glorious and world-wide brotherhood. In illustration of what I mean, I fell ill in a small town in Germany. A physician attended me with much care and skill. When he learned that I also was a physician he would not allow me to give him any fee. He said: "Sir, I was ill in St. Petersburg and a good doctor took care of me and would take nothing from me, and so you will pay me by taking care of some other in that far country of yours across the sea." The records of these things are not written in the books of this world. This guild of which I have spoken possesses a creed drawn from the morals of Christianity—honor, chastity, brotherhood, and charity. As to the charity, I ask what lawyer would sit down twice a week and give a couple of hours' advice to any who might come and ask it, and do this for nothing? What merchant would say to a needy customer, "I propose to present you with these goods?" Yet it is a fact that two thirds of the physicians of eminence give two or three hours, sometimes daily, to this kind of labor, when the experience to be gained from it has long ceased to be of benefit to them. This kind of work is not fully understood by the public, or they would be more willing to come forward and assist us in return by aiding our great libraries in such purposes as we are endeavoring to carry out around you to-night. I must not only on my own part congratulate the fellows of the Academy upon the completion of this work, but also offer the warm congratulations of the members of the Philadelphia College of Physicians. I have been of late their president, and from them I carry this message. I was asked the other day by two very intelligent laymen, to whom I was showing our medical library, why the profession needed such a vast collection of books, and whether such were not simply the graveyard of theories and the record of what was now useless. I replied that, while theories died, facts remained, and had their vital uses to-day, and might be quoted; therefore a great library was a great museum of facts which remained to us permanently. A medical library showed the history of the profession, which had its joys, its sorrows, and its romances, and upon its shelves might be found the record of what the profession had done in the past and the indications of what would be done in the future. When the physician of this or any other great city ceases to desire to be learned and accomplished in a great many ways, and is ready to forget the honorable traditions of his profession, and is beginning to look upon it as merely a business, then he will have taken that one fatal step toward degradation, a step from the high level to the lower one of a merely useful trader.

Remarks of Dr. Reginald H. Fitz, of Boston.—Mr. President and Ladies and Gentlemen: To find myself a guest on so memorable an occasion as the present is a privilege I can not value too highly. My feeling, however, is not one of unalloyed pleasure, since a sense of envy arises as I see commodious and comfortable appointments which are to serve in the future as one of the many medical centers of your city—one which I feel will not be the least to unite in harmony members of our profession and make us ever mindful that a common aim, the welfare of suffering humanity, is the chief object of a physician's life. But my sense of envy is somewhat blunted as I am reminded that the success of your efforts may be attributable in some measure to the inspiration which may have been derived from the city I represent. My friend, Dr. Chadwick, reminds me that not many years ago, a few months before you were congratulating yourselves and were being congratulated upon the possession of a new library hall, your president of that time, the honored Dr. Fordyce Barker, visited Boston. He came to see how we dedicated a new library building. He learned so much that after his return he was able to say to you that, if you proved worthy of your trust, still better things might come to you in time. That he was no false prophet he who comes may see. May my visit to New York be followed by as brilliant a result as his to Boston! On that memorable occasion when, in 1879, your library hall was dedicated, Boston was represented by one of its distinguished physicians, Professor George C. Shattuck. He was about to tell you what we had been doing to obtain a suitable building for a medical library—one which might also serve as a meeting house for physicians, where they might forget their disagreements and be stirred to the accomplishment of better things. New York's hospitality was so pressing that before his story was completed I find he was invited to partake of the loving cup. What that may have meant I must ask those of you who were present to recall. I may perhaps be permitted to finish what he began, though neither so well nor so completely, but the tale may act as a suggestion that may not prove to be without profit.

The Boston Medical Library serves pre-eminently as a medical center for our city. It contains our largest collection of medical works and periodicals. In its rooms the various medical societies meet, and its hospitality is offered with the greatest freedom to all those seeking its aid. In these respects it may follow closely your footsteps. For the community in which we live it does something more, a work that is perhaps better appreciated by the sick patient than all the rest—it furnishes a home for the Directory of Nurses. This means that at any time, night or day, in reply to messenger, telegram, or telephone call, a suitable nurse for any sort of ailment will immediately be sent to the houses of patients, whoever they may be, at a trifling charge. Nurses have been so sent throughout New England, to Carolina and Florida, to Colorado and California, possibly to New York. In the past year nearly two thousand nurses were thus supplied. The directory is an immediate benefit to the library, as the income is so far in excess of the expenditure as to constitute a considerable financial support to the needs of the library. Its convenience to patients and to physicians, as well as to nurses, has made it a necessity, it has come to stay. I have made the story as short as possible, and, though your present surroundings suggest that you are in no need of financial support, such an undertaking I am convinced you would find, on trial, a convenience which would make your influence as a medical center even greater than now seems possible.

I thank you for your welcome and attention, and shall return to my city encouraged, trusting that the day is not far off when Boston will follow your example in providing a medical center worthy of its profession and wealth such as this, which is a monument to the influence of such men as Jacobi and Loomis, and to the generosity and public spirit of its philanthropic citizens.

Remarks by Dr. Fordyce Barker.—Dr. Barker said: Mr. President and Fellows of the Academy: I must detain you only a few moments on this joyous occasion to express my warm congratulations. It is now nearly twelve years since I had the honor first to address the Academy officially, when I expressed the hope that the walls of our then home would soon be extended for our rapidly growing library. Within a few months after, by the spontaneous gift of one whose name must ever be gloriously perpetuated and now honors one of the rooms in the present building, our house was greatly and beautifully enlarged, and met all our wants for several years, until it became apparent that we must have more room for our books and the other requirements of the Academy.

To most of us this probably seemed a dim perspective in the future. Who could have expected so speedy and noble a result as we now see? We can now say appropriately, in a

paraphrase of the words which Shakespeare put into the mouth of Gloster, in Richard III: "Now is the winter of our discontent made glorious summer" by these our sons of York.

I must congratulate the Academy on its office-bearers, all of whom must have worked most zealously to bring about this happy result. And I especially congratulate it on its wise election of the present incumbent of the presidential chair and his immediate predecessor, both of whom have labored together with untiring earnestness, great wisdom, and tact, and both of whom possess means which they have liberally contributed to this end. I do not hesitate to express the opinion that without the combined efforts of these two gentlemen the glorious consummation which has now arrived would have been long delayed.

We have now a central and spacious home in which the profession will find it pleasant and profitable to work together for mutual improvement and the public good in the advancement of science, the promulgation of new truths, and the development of progressive skill in our art, and, I will add, the cultivation of those social graces which bind us in the friendly ties of brotherhood in a noble and useful profession. We can assure the profession that they will be welcomed to a library which contains the accumulated treasures of the past on every topic pertaining to medical science, and the current periodical literature of the day, so necessary for all who would keep abreast with the present rapid advance of science.

We to-night begin a new era of the New York Academy of Medicine. Who will venture to cast a horoscope of its grand future? New York, the commercial metropolis of the country, should be the metropolis of the medical thought, the medical literature, the medical teaching of the country; and to the Academy of Medicine belongs this great mission.

One thing we should all remember—that above there is room for an additional hundred thousand volumes. Ever bear in mind that *concordia res parvæ crescent, discordia res maximæ dilabuntur;* and the future we seek for this Academy is certain to be gained.

Letters of Regret were read by the president. Dr. L. L. Seaman had written: In congratulating the Academy upon the acquisition of its new home, I beg, through you, to present to its members a statue of Esmeralda, hoping that within this new temple of science Art may ever find a most generous welcome.

The Hon. Grover Cleveland regretted that a previous engagement prevented him from being present on an occasion so full of interest.

Dr. Henry I. Bowditch, of Boston, closed his letter with the wish that the New York Academy of Medicine might continue the powerful influence in the future that it had had in the past for the uplifting of the whole profession of America.

Dr. N. S. Davis, of Chicago, closed his letter with this sentiment: The event you celebrate marks another illustration of the maxim that in union and harmony there are both strength and success.

Dr. Bacon, of New Haven, wrote: As in the past, we shall in the future watch the doings of and receive inspiration from the New York Academy of Medicine.

Dr. W. H. Welch, of Baltimore, wrote: I feel confident that the new era inaugurated by taking possession of your new building will be one in which not only the members of the Academy, but also the entire profession in New York and the whole country will take pride.

Dr. Oliver Wendell Holmes wrote: I regret that I can not be present at the opening reception at your new building, but in one sense I shall be among you, for the whole of the medical profession will be with you in spirit and fellowship. Academies have too often been thought of as places of honorable retirement and dignified ease—roosts where emeritus professors and needy men of letters, once cocks of the walk, could sit in quiet rows, while the fighting, the clucking, and the crowing were going on beneath them. No doubt to be a member of the French Academy—one of the forty immortals—is an honor worth striving for, in spite of Piron's epigram. But the academy which fulfills its true function is a working body which deals with living subjects; which handles unsettled questions; which sets tasks for its members and furnishes, so far as it can, the appliances required for their prosecution. It offers rewards for meritorious performances, and sits in judgment upon the efforts of aspirants for distinction. It furnishes the nearest approach we can expect to a fixed standard of excellence, by which the work of new hands and the new work of old hands can be judged. It is a barrier, a breakwater against the rush of pretensions which are constantly attempting to find their way into the public confidence. Nowhere is such a defense more needed than in the science and arts which deal with the health of the community. The public is so ready, so eager to be deceived, and the adepts in deception are so willing, so hungry to deceive those who will listen to them, that it needs a very solid wall of resistance. The various forms of what I will venture to christen as psendopathy and psendo-therapy—though they are known to the public by other names—can never loosen the hold of the thoroughbred and intelligent physician on the intelligent members of society so long as the best heads of the profession are banded together in a noble institution like this Academy. Only let it ever remain steadfast.

We look to this great and able body of men to guard the sacred temple of Science against the worshipers of idols. The medical profession will always have to fight against the claims of the wrong-headed. There is a certain number of squinting brains, as there is of squinting eyes, among every thousand of the population. There will always be a corresponding number of persons calling themselves physicians ready to make a living out of them. Long may it be before the wholesome barriers are weakened that separate the thoroughbred and truly scientific physician from the plansible pretender with his pseudopathy and his pseudo-therapy. We trust it will be always enough for the physician to be able to say, "I am a member of the New York Academy of Medicine."

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of October 8, 1890.

The President, Dr. Charles K. Briddon, in the Chair.

A Contribution to the Study of Appendicitis.—Dr. Lewis A. Stimson read a paper on this subject. (See page 449.)

Dr. Charles McBurney said he would speak for a moment on that class of cases which were being constantly held up by physicians as ending in rapid recovery with comparatively mild symptoms and without calling for operation. These mild cases were numerous, and one physician might, in his practice, come across some three or four of them and draw his conclusions therefrom. Another, with a large practice, might not meet with any cases of appendicitis. The speaker had tried to formulate some definite rules to enable one to decide at once if the case presenting was one which required operation or one that could safely be treated by conservative measures. He was obliged to say that he was, as yet, unable to lay down any defi-

nite rules for his own guidance or that of others who might desire to study the subject. Much was to be learned from the general expression of the patient as to the existence of steadily advancing disease. The character of the pulse in almost all cases gave a considerable amount of information and was in some instances more important than the temperature. The latter was a very unreliable diagnostic sign. Sometimes it would remain below 100° F. while suppuration was becoming pretty well advanced. Again, the sensations of pain were not of great value. The length of time elapsing since the seizure, taken in connection with the general symptoms, would often help ot decide the question of operation. He had operated at various stages, at the end of the first, second, and third day, and had thought that it was often admissible to allow thirty-six hours to pass before deciding upon an operation. Very few accidents were likely to happen during that time. If this period was passed and there was no increase in the symptoms, and the pulse was nothing more than a moderately feverish one, then the question of operation might be delayed or given up. But, again, it was true that following such a rule might be a very unfortunate proceeding, for early perforation, with septic peritonitis, might take place. Still, he thought such conditions might be recognized by the general symptoms, which would sharply define them from a case that was steadily improving. Something definite, however, was needed to mark the line between the cases which bid fair to end in recovery and those which did not, in order to encourage operative procedure where it was indicated. He would like to see further information forthcoming on this point. He had within the past year seen twelve cases which had been mild from the beginning and, within forty-eight hours, had become still milder in character, and the patients recovered rapidly without operation. In these the operation had not seemed called for. As to the question of recurrence of the disease with increased severity, say five or six attacks, many medical men asserted that the recurrent condition was a favorable state of things, and that such cases were not likely to end in perforation. He would cite the case of a young man who had had three or four attacks of appendicitis of marked severity at intervals of a few months. This patient had been under careful observation by competent men. The speaker had seen him at the end of the third attack, when he was getting better. An operation was not urged, as it seemed clear that no pus had ever been present. It was supposed that very strong adhesions had formed around the appendix, which would protect the peritonæum in case of another attack. Subsequently another attack had come on, and the character of the symptoms was, this time, so alarming as to call for prompt operative interference. Instead of adhesions, there was only one, and this was not recent. In a little pocket formed between the appendix and the colon there were about three drachms of pus. It seemed evident that if the patient had even turned over in bed he would have spilled this material into the pelvic cavity. He would like to mention one rather striking fact. No one who had ever seen these operations could have failed to note how exposed the adjacent peritoneal tissues were to septic infection from instruments and sponges, no matter how great the care taken to avoid this. Still, it was a fact that septic infection seldom arose from this cause. He did not know the reason. Perhaps the relief given from the tension and the resulting improvement in the circulation allowed the patient to dispose of a moderate amount of local sepsis.

Dr. F. Lange said his experience in these cases was of course not so great as that of the last speaker. Though he had in a good many cases operated for perityphlitic abscess, he had only in five cases excised the appendix after free laparotomy, and he was rather inclined to temporize. Free opening of the peritoneal cavity in encysted perityphlitic abscess was always a dangerous operation, and wherever it could be abandoned in favor of the usual incision of older date, it must be to the advantage of the patient. It must not be forgotten that in former years by far the majority of these cases, under cautious treatment, had been cured by simple incision. On the other hand, there were cases in which the radical operation could not be done too early, and the difference in the virulence of the infecting agent must be very great in the various cases, if one saw that there were cases which would end fatally in forty-eight hours by acute septic poisoning, and, on the other hand, those in which there were large quantities of pus with no serious disturbance of the general condition. In some of his own cases, as well as in several others, where he had acted as consultant, he had been struck by the advanced stage of destruction compared with the short time after the onset of the severe symptoms. By the middle of the second day there had been found, not only perforation, but extensive destruction of the appendix and far-gone infection of the peritonæum. In such cases the destructive process in the appendix, perhaps a circumscribed formation of pus around it, must have preceded, and the bursting of such a formation must have given rise to the diffuse peritonitis. In other cases the state of things was quite different. After repeated attacks, the operation might reveal the fact that no formation of pus had ever taken place, as Dr. McBurney had just cited. He recalled the case of a young man, about eighteen years of age, whom he had presented to the society about two years before, on whom laparotomy had been done twice. The first operation showed the ascending colon constricted by adhesions and bands. The appendix was not found, as it was imbedded in a thick cicatricial body behind the colon, and ileocolostomy was done, since it was assumed that perhaps the narrowness of the colon had been the real cause of the attacks. The patient made a good recovery, but the attacks did not cease. Another laparotomy, with careful dissection of the hard mass behind the colon, brought to light the dilated and thickened appendix with an almond-shaped fæcal concretion in it, but nowhere the slightest indication of any formation of pus or disintegration of the walls of the appendix. The patient made a good recovery and was now in perfect health. This case was the first one of operation in New York in the quiescent stage. In this case the attacks had probably always been due to an accumulation of inflammatory material within the appendix, and the attacks had ceased by the discharge of the fluid into the gut. Though in most of his five cases, four of which had ended in recovery, he had found fæcal concretions, it was not quite probable that these mostly rather hard, smooth bodies had been the direct cause of the attacks.

The most difficult question in the treatment of certain cases of perityphlitis in which the operation was advisable was with regard to the temporarily reduced general condition of the patient. Some of these patients would surely die if not operated upon; in some the operation might be the immediate cause of death. Would the patient stand what ought to be done? To decide this question was, in his opinion, one of the most difficult tasks in surgery. An apparently diffuse peritonitis would sometimes become circumscribed, though several foci of pus might be formed. He had repeatedly in this society cited his experience in cases where extensive suppuration had taken place and several openings through the abdominal and rectal walls had had to be made. He was, however, not able to give any distinct rules according to which in some of these cases a temporizing treatment was preferable, while an early operation might kill the patient. The pulse and general expression of the patient gave a certain ground for judgment, but it was always unsafe,

and probably would always remain so, since the infectiousness of the poison and the resisting power of the body were two factors which might be guessed at, but for which no safe standard could exist. Contrary to Dr. Stimson, he had found perforation in those of his cases where suppuration was present. To illustrate how minute sometimes such a perforation might be, a specimen of appendix was shown.

Dr. Parker Syms said that the opinion held by physicians that many patients with appendicitis recovered without surgical interference was of course a correct one; but in this connection he would call attention to the fact that error in diagnosis was frequent. He had met with two such instances recently.

Dr. Lewis S. Pilcher said that, after listening to the paper read a year ago by Dr. McBurney, he had been observant of cases which might be appendicitis, with the view of making the diagnosis in the early stages and appreciating the symptoms calling for operative interference. During the year he had met with quite a number of cases, but in one case only had the indications been such as to warrant early operative interference. In one he had been in doubt, and had desired that a little longer time should be given him before deciding. On the second day another consultant was called in, who also requested a little time. This second delay had proved fatal, for before a decision was arrived at the patient had died. In other cases he had had no hesitation in advising that no operation should be done, and resolution had taken place. Such resolution, without the formation of abscess requiring operation, had formerly been a frequent experience with him when he had been engaged in general practice. During many years he had not met with a case of appendicitis which had not, under proper treatment, given satisfactory results. Since his cases had been carefully watched, so that he could be reasonably sure there was no mistake in diagnosis, he was bound, as the result of his own experience, to adhere to the doctrine that many inflammations in the region of the appendix would result in resolution without operation. In one recent case such resolution had, after some months, been followed by a second attack, which had resulted in suppuration, requiring incision. In yet another case, which he had seen at the beginning of the third day and within a few hours after it had first been seen by any physician, there was no tumor, but the localized tenderness, which they should be pleased to recognize as the McBurney symptom, was distinctly marked. Symptoms of rupture of the appendix and septic invasion of the peritonæum were pronounced, and the general septic intoxication was severe. The necessity for prompt interference was manifest. He had not felt justified in refusing to operate in this case, notwithstanding the little prospect of benefit which it gave. The region of the appendix was exposed, and the organ was found buried in a mass of dense adhesions. The right iliac fossa was filled with a quantity of thin, ichorous, puriform material. The adjacent intestines were also covered by exudate, but not yet adherent. The patient was temporarily improved by the operation, but afterward succumbed to the septic condition existing before the operation. The post-mortem demonstrated that all the accumulation of septic material had been removed and that drainage had been efficient. In still another case a typical perityphlitic abscess had formed, which had opened into the bowel before he saw it. This internal drainage had, however, been inadequate, and he had been compelled to make an incision through the groin, after which the abscess had healed quickly.

The President said that, as to the innocuousness of a given amount of pus in certain cases where the peritonæum was exposed to infection during an operation, he believed it had been demonstrated that this region could take care of itself against a certain amount of septic material, provided the focus from which the material was secreted was removed in time. In experiments on animals a certain amount might be introduced; the temperature rose, but the animal recovered. But, if the material was in large quantities, general sepsis took place. If only a limited quantity was used, or the focus of infection was removed, it would not produce general peritonitis of a fatal character. He thought that the treatment of these appendicitis cases by thorough drainage and the use of such dressings as iodoform gauze had a great deal to do with the happy results obtained. As to the pulse, he thought that, when pus formed in the pelvic cavity to a limited amount and became encysted, the temperature fell.

Dr. Lange took exception to the term "resolution" which Dr. Stimson had employed for cases which seemed to end in spontaneous recovery, and asked in what sense he had used it.

Dr. Stimson replied that he had used it in the sense in which it was sometimes employed in connection with other inflammations—namely, to indicate the subsidence of inflammatory symptoms without the evacuation, and apparently without the formation, of pus. He believed, however, that such subsidence was not proof that pus had not formed. He thought a small amount of pus might be absorbed.

Dr. McBurney doubted whether the pus was ever absorbed. He had found it many months after in patients who had been comparatively well in the interim. He believed that many of the cases were those of moderate inflammatory action. There was a certain amount of infiltration. The appendix became swollen and there was strangulation of the blood-vessels, with general interference with the circulation of the organ. If the circulation became re-established and the patient got well, the process might be not inaptly termed resolution.

Dr. Stimson thought that the fact that pus was found as stated was no proof that it was never absorbed. It was known that the cellular elements of pus might undergo a molecular degeneration which fitted them for absorption.

Dr. McBurney showed an appendix, recently removed, in which there was a well-marked gangrenous area surrounded by comparatively healthy tissue. Within the organ there was a small fæcal concretion, which probably accounted for the original irritation to the mucous membrane, the strangulation of the vessels, and the resultant gangrene.

Exostoses of the Femur and Enchondroma of the Metacarpus.—Dr. Lange exhibited a specimen of extraordinarily large and irregular exostosis bursata which he had removed with the chisel from the femur of a young lady in whom the growth had existed for a great number of years; also a specimen of apparent exostosis of the metacarpal bone of the second finger, which had proved to be an enchondroma.

Prolapse of the Rectum; Operation; Recovery.—The President reported the following case: Emma H., aged thirty-two, married; no morbid family history. General health had always been good. Her present trouble dated back to an early period of childhood. With every defecation there had been a protrusion of the bowel through the anus, the condition being much aggravated when the bowels were constipated. When riding, traveling, or engaged in other active exercise, the patient had always had a feeling of insecurity due to a partial loss of control over the sphincter. She had had one miscarriage and one normal labor nine years ago. For a period of two years following the birth of her child she had suffered little inconvenience from the prolapse. Her symptoms had all returned, however, and seven years ago she had undergone the operation of linear cauterization, which was followed by temporary relief. Her symptoms had again returned and she desired a cure by operation. The perinæum having been shaved and scrubbed and the parts made aseptic, the prolapsed mass,

five inches long, was drawn down through the anus and thoroughly exposed, a procedure easily accomplished owing to the relaxed condition of the sphincter. The patient was then placed upon the back with the thighs separated and elevated as in the lithotomy posture. An incision was made transversely through the mucous membrane on the anterior aspect of the prolapsed gut, a little below the verge of the anus. The dissection was then continued, the hæmorrhage being checked with clamps. The peritoneal pouch of Douglas was then opened. The danger of infection at this stage of the operation was minimized by frequent irrigation with Thiersch's solution. The peritoneal cavity was then closed off by uniting the two opposed serous surfaces by Lembert sutures of fine catgut above the line of division. The prolapsed portion of rectum was then ligated *en masse* with an elastic ligature and cut away with a few sweeps of the scalpel, and the proximal end of the gut slipped up within the anus. It was brought down, and, after the application of a very large number of ligatures, which were required to control the hæmorrhage, its mucous membrane was sutured with silk to the mucous margin of the anus. The sutures last introduced were left long, the ends hanging from the anus. The site of operation was irrigated, a morphine suppository inserted, and the operation completed by the application of an antiseptic dressing and a T-bandage. The portion of gut removed measured over five inches in length. There was some rise of temperature on the third day, with nausea, eructations of gas, and tympanites. The patient had convalesced steadily and regained perfect control over the rectal sphincters.

Umbilical Hernia; Operation; Recovery.—The President also reported the following case: Frances P., aged forty-seven, housewife. Eight years ago she had an attack of right hemiplegia, from which she had fully recovered in two years. She had had five children, her confinements being easy except the last, eight years ago, when she was in labor for three days. Shortly after the birth of her last child she sustained a severe strain from a fall, and three weeks later she noticed for the first time a slight bulging at the umbilicus. The tumor increased in size, and she consulted a physician and was advised to wear a pad and binder. In spite of these supports, the tumor continued to grow and had recently become painful and tender. There had been no vomiting or disturbance of the bowels, and her appetite was good. There has been a marked loss of strength, but no emaciation. The patient had come under the speaker's care at the Presbyterian Hospital, where he had operated as follows: The abdomen having been well scrubbed and made aseptic, the patient was put into the dorsal decubitus and the site of operation surrounded with aseptic towels. An elliptical incision was begun two inches above the tumor, carried entirely around it, and prolonged to the same distance below it. There was a very thick layer of abdominal fat, and the dissection was continued down to the fascia of the abdominal muscles, exposing the neck of the sac and at one point accidentally making an opening in the sac, through which a mass of omentum protruded. After carefully isolating the neck of the sac, the peritoneal cavity was opened and the contents of the sac were explored. They were found to consist entirely of omentum, the pedicle of which was ligatured and the entire mass cut away. The abdominal viscera were held in place by means of a hot antiseptic sponge in the wound, and the incision in the peritonæum was closed with interrupted sutures of stout catgut. The incision in the abdominal wall was then closed by a double row—deep and superficial—of interrupted sutures, drainage being provided for by the insertion of one medium-sized tube in the most dependent portion of the wound. The parts were irrigated and the operation was concluded by the application of an antiseptic dressing and a snug binder. The patient made an uninterrupted recovery and, a month later, was fitted with an abdominal supporter.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of November 4, 1890.

The President, Dr. Landon Carter Gray, in the Chair.

Astasia and Abasia.—Dr. G. M. Hammond showed a young woman who had never been the subject of any serious illness excepting Pott's disease, which had come on during childhood. Over a year ago the speaker had attended her through an attack of nervous prostration. During her illness she had suffered from aphonia. The difficulty in standing and walking was not discovered until she was able to leave her bed. On her regaining her strength sufficiently to walk around, it was observed that she invariably walked by first advancing the left leg and then drawing the right one up to it. When she attempted to walk naturally, immediately that the right foot touched the ground her body would revolve rapidly to the right, when, after making a revolution and a half, she would sink to the floor. Physical examination of the limbs revealed nothing abnormal. The patient while seated or lying down could move both legs normally; with the right leg, however, more mental effort was required to make the movements. The patellar tendon reflex was normal on both sides. There was no ankle clonus, anæsthesia, hyperæsthesia, or any other disorder of sensibility in any part of the body with the exception of slight loss of the muscular sense in the right leg. The electrical reactions, both qualitative and quantitative, were normal. The field of vision and the color sense were found normal. The senses of hearing, touch, pain, and temperature were tested without anything abnormal being discovered. There was some resistance to passive flexion and extension of the right leg. Those symptoms, then, of difficulty in standing and of inco-ordination and ataxia of movement for the act of walking, but not for other muscular acts, corresponded accurately to the condition described by Bloeg under the title of astasia and abasia. Bloeg was of the opinion that astasia and abasia was a condition pathologically similar to agraphia. The speaker did not see anything in these cases to substantiate this view. People afflicted with the disease under consideration could make the motions of walking perfectly well if they were allowed to lie down, but it had never been maintained that an individual suffering from agraphia could write any better in one posture than in another. The condition, it seemed to the speaker, depended upon a loss of the power of adjusting muscular contractions so as to maintain an exact equilibrium. This was, of course, a defect of the muscular sense. There was no known tract in the spinal cord disease of which would be followed by these symptoms. Bloeg had attempted to make a distinct neurosis of this class of cases, and maintained that a diagnosis between hysteria and astasia and abasia could readily be made. In the latter disease there were no hysterical stigmata, he stated, no constant paralyses or constant contractures. But the latter were by no means characteristic of all cases of hysteria, and when it was considered that every case of astasia or abasia had been accompanied by some other symptom or symptoms, such, for example, as hyperæsthesia, anæsthesia, aphonia, contraction of the visual field, and temporary color blindness, all of which frequently accompanied hysteria, and since the disease under consideration was purely functional in character, no macroscopical or microscopical lesion ever having been discovered in it, it would not be difficult to believe that astasia and abasia was merely an uncommon type of an hysterical affection.

Dr. C. L. Dana said that, if it was possible to exclude any organic trouble as a factor in the case, there seemed nothing

left but to give the condition the name which Dr. Hammond had used. It was by no means certain that this so-called disease deserved a separate clinical position, and all the vagaries of the trouble were by no means known. He thought that the diagnosis might be accepted as a provisionally correct one.

Dr. Louise F. Bryson said she had recently been reading a case reported in a French journal of what was known as "left- and right-sided disease," in which the patient always had to walk to the right. Physiologically, the muscles of the right side were stronger than those of the left, and perhaps the case was one of exaggerated function of the muscles of the right side.

Dr. G. W. Jacoby said that in a recent number of the *Berliner klinische Wochenschrift* Dr. Binswanger had stated his belief that the whole trouble resulted from a psychical condition, as the same phenomena were found in other mental states. He had not seen a case exactly like this, but others which reminded him very much of it. He was inclined to consider the condition as a psychic manifestation. Women, after long confinement in bed, would sometimes, when attempting to walk, find themselves too weak to do so, and immediately conclude that they had lost the power. While lying down or sitting, they had entire control of their limbs, but when they essayed walking, then came the fear. It was a psychic disturbance of equilibrium. He thought that Binswanger had done as much to clear away doubt in this class of cases as others had done to produce confusion.

The President said he had never seen anything like this case. The cases of hysterical paralysis that he had seen had been typical forms of paraplegia. He had also read the two cases described by Russell Reynolds, who had called them "paralysis of idea." He did not think it was well to designate this case as one of hysteria on account of the presence of some spots of anæsthesia, because it had been shown that this occurred in a great many different nervous disorders, both functional and organic. It seemed better to accept the case as a clinical entity and hold any opinion in reserve as to the cause of the manifestations.

Syringomyelia.—Dr. J. C. Shaw presented a single woman, thirty years of age, who had always had good health until about six years ago, when a weakness of her left hand was noticed. This condition had steadily increased up to the present time. For the past three years she had had a constant aching in the left arm, shoulder, and side of the neck, and lately on that side of the head. For two years there had been a numb spot on the inner side of the left arm. She had constant sensations of burning on the left side of the face and neck, with flashes of heat and cold. There was a small spot on the back of the head where this burning sensation was greater than anywhere else. She presented an atrophy of the small muscles of the left hand, which had existed for six years, and was gradually growing worse. There was also slight atrophy in all the muscles of the left arm, shoulder, and side of the face. In the area of the numb spot the tactile sensibility was impaired. The thermic sense was greatly diminished over the entire left side, and in the right lower extremity as well. The reflexes were exaggerated. While the examination of the patient had not been as careful as it might have been, the speaker thought that it was sufficient for the purpose of diagnosis.

Dr. B. Sachs thought the personal equation was a powerful factor in this case. It certainly had been so that evening. The case did not seem to him to be one of syringomyelia. The atrophy was not marked enough, particularly about the shoulder. The sensory symptoms were not so distinct as in a typical case. So far as he could judge, the case seemed one of amyotrophic lateral sclerosis, though further examination or observation might lead him to a different conclusion.

Dr. M. A. Starr said that there were several features about this case which reminded him of one that had come under his observation. He had not brought these points out, because he did not know that they belonged to syringomyelia. One of these peculiarities was the noise made in the throat—a sound as of alarm. This had been present in his patient, who was by no means a hysterical girl. He had regarded it as due to a muscular contraction of the larynx during inspiration. His patient would make the noise whether she was quietly conversing in his office or was before a class of students. This feature was to be taken into consideration. He thought that the stationary condition of the atrophy in this case indicated the existence of syringomyelia rather than that of amyotrophic lateral sclerosis. He had demonstrated pretty conclusively the changes in the pain-sense by sticking the point of a needle into the patient's arm without her knowing it. There was no mistake about it, for he had put the needle in a quarter of an inch. Then there was the history of a loss of temperature sense. The patient had noticed in putting her hands into hot water that there was a difference between the two sides. Therefore, bearing in mind the non-progressive condition of the atrophy and the existence of changes in the temperature and pain senses, he supposed one was warranted in making a diagnosis of syringomyelia.

Dr. Sachs thought the question depended upon the actual condition of the sensory derangements in this case, and, of course, the examination had been but cursory.

Dr. W. R. Birdsall thought that where the results of examination were so at variance it would be hardly worth while to attempt any expression of opinion in the way of diagnosis. It had been his impression, from the descriptions of cases of syringomyelia which he had read, and in which an autopsy had been held as confirmatory evidence, that the histories had given the pain and temperature sense as having been both affected. He should say that the case before them was at least typical in this respect. As to this disease, it was a remarkable fact that, during the past year, of the cases in which syringomyelia had been diagnosticated during life there had been no autopsy, while in those autopsies which had revealed the existence of the disease its presence had not been suspected during life.

Dr. Dana said that last spring he had had a patient in his hospital service who had presented many similar symptoms. There had been atrophy in the muscles supplied by the ulnar nerve and of the small muscles of the hand. There was also anæsthesia involving the temperature and pain senses. The atrophy had slightly involved the opposite side. There was also a belt of anæsthesia over the lower portion of the trunk, and extending to the thighs. There was no disturbance of the sensory functions. The girl had gradually developed symptoms of bulbar paralysis without any sensory symptoms accompanying. He had been obliged to regard this as a typical case of progressive muscular atrophy. He had since seen a case of progressive muscular atrophy in which sensory symptoms were present. If the symptoms of bulbar paralysis were developed in the case before them, it would, he thought, turn out to be a case of progressive muscular atrophy. As to amyotrophic lateral sclerosis, it was simply another name for the same disease.

The President said the only way to make a diagnosis of syringomyelia seemed to be to make an autopsy. The value of the loss of thermic sense in a patient as a diagnostic point was, to a great extent, vitiated by the fact that the relations of this sense to other organic spinal diseases were unknown. He thought it would not be possible to establish the fact satisfactorily that this was a case of syringomyelia until the woman died.

Spina Bifida, with Suppurative Meningitis and Ependymitis of Bacterial Origin.—Dr. L. Emmett Holt and Dr. Ira

Van Gieson reported a case of spina bifida in an infant in which the entrance of bacteria into the wall of the sac had apparently caused suppurative spinal meningitis and ependymitis. The child had died at the age of three weeks, having had paraplegia, marked irritability, and failing nutrition. The center of the spinal sac had the appearance of a granulating surface and was covered with a sero-purulent discharge. There were no physical signs of hydrocephalus. At the autopsy the ventricles of the brain were found to be greatly distended with thin pus. The pons Varolii and the cerebellum were partially covered with a yellowish exudation, also a portion of the spinal cord and the whole interior of the sac. There were great numbers of small cocci, in chains, in the wall of the sac, in its inner coating, in the central canal and meninges of the spinal cord, in the exudition on it and the pons and cerebellum, and in the walls of the lateral ventricles. The microphyte seemed to be the *Streptococcus pyogenes*. Dr. Holt said he had seen one other of these cases of hydrocephalus in which the disease had existed without any symptoms during life. He thought there were probably a great many more than was usually supposed. He had been surprised to find that the ventricles contained several ounces of fluid. He had seen several cases of basilar meningitis in which only a moderate amount of distention of the ventricles was found. In two of these cases the entire contents of the lateral ventricles would not have exceeded an ounce.

Cerebral Compression.—Dr. E. D. Fisher read a paper with this title. He said that, while he had nothing new to present, he thought that he could settle definitely the question of the influence of compression on the cerebral mass within the skull, and whether the cerebral substance was, *per se*, compressible without interference with its capillary circulation or function. Bergmanns and Adamkiewitz held that the brain substance was incompressible, the only conditions of change possible in the cerebral volume being those dependent on the displacement or variation in the cerebro-spinal fluid or the cerebral circulation, these standing in converse relation to each other. The question of the compressibility of the brain depended on which of the elements comprising the brain was most liable to compression; as the blood-pressure was higher than that of the cerebral fluids, it was possible that the tissue fluids were first affected. Much depended also on whether we regarded the liquor cerebri as a secretion or as a transudation from the blood-vessels, as in the latter case we should have to consider arterial tension as a very important factor in cerebral compression. The vascular center was situated not only within the medulla, but probably also within the brain—*i. e.*, the corpus striatum or optic thalamus. The brain possessed a mechanism of its own for increasing its blood-supply independently of increased cardiac action. Experimentally it had been proved that cold acted deeply within the brain. Its good effect was very marked in the headaches of anæmics, the ice-bag being an efficient remedy. The cold probably acted by increasing the blood-current rapidity in the capillaries, and by causing spastic contraction of the arteries. In these cases the amount of blood passed through the brain by increasing the rapidity made up in quantity for the quality, thereby maintaining the nutrition. The extent of a cerebral hæmorrhage depended on the arterial pressure or tension, the intracerebral pressure, and also on the resistance of the brain substance, the latter, of course, depending on the site of the hæmorrhage. Spastic contraction of the arteries of the brain really caused active hyperæmia, the decreased volume of the skull contents causing increased capillary circulation. Paralytic dilatation of the arteries caused passive hyperæmia, which was, in fact, anæmia, the blood being no longer in a proper state to carry on the nutrition of the brain, as the increased volume of the brain caused retardation of the capillary circulation, and probably also interfered with the venous circulation. The speaker's experiments had been made by exposing the pia mater and observing the changes produced in the blood-vessels. Extension of the sciatic nerve produced increased volume of the brain. Compression of the carotids caused marked loss of volume. Asphyxia caused expansion of the brain. Chloral caused anæmia, with marked contraction. Chloroform contracted the brain. Ether at first contracted and subsequently expanded it. Strychnine caused marked expansion, as did digitalis and small doses of alcohol. Caffeine and the acids caused expansion, while the alkalies produced the reverse result. From his experiments the speaker concluded that the blood-supply of the brain varied directly with the blood-pressure in the systemic arteries, and that the extensibility of the walls of the cerebral vessels allowed of great variation in caliber. The vaso-constrictor centers were excited directly by disturbance of the nutrition of the nervous system, as in anæmia, asphyxia, etc. Finally, the essential product of cerebral metabolism contained in the lymph-spaces bathed the walls of the arterioles and could cause variations in the caliber of the vessels, this mechanism reacted on the brain, and by this means the vascular supply could be varied locally according to local varieties of functional activity.

Dr. G. W. Jacoby said that the demonstration that the nerve tissue could be compressed in its molecules and anatomical elements had been professed by one author. Another had maintained the non-compressibility of these elements, but had further stated that the effect of hæmorrhage was due to anæmia of the brain. This was, as a theory, substantiated by comparing the clinical symptoms in such hæmorrhage with the symptoms caused by injecting lycopodium powder into the cerebral vessels, and producing thrombi. He then referred to the experiments of one who had demonstrated the displacement of the cerebro-spinal fluid. In one case in which rice was injected the aqueduct of Sylvius was found to be ruptured, and the lateral ventricles were flattened together. This experimenter had inferred that the very suddenness with which the compression was exercised had caused the violent displacement of the cerebro spinal fluid and consequent rupture. The same observer had also estimated very minutely the amount required to oppose the arterial tension, and had maintained that, if at any time an effusion took place on the surface of the brain to entirely balance this, death must result instantly. Dr. Fisher had pointed out the necessity of maintaining arterial tension, rather than depressing it, upon this very theory. It had been suggested that in cerebral hæmorrhage the head should be hung down to send blood to the head mechanically, and thus oppose the effusion which was taking place from the ruptured vessels. He did not know whether this had ever been put into practice.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNÆCOLOGY.

Meeting of October 22, 1890.

Dr. E. H. Grandin in the Chair.

Hermaphroditism.—Dr. J. K. Crook described a case of hermaphroditism which had recently come under his observation.

Dr. Grace Peckham said that last spring she had occasion to see a woman whose external appearance was entirely masculine and in whom the genital organs were of a more pronounced male type than those described in the case of Dr. Crook. She had seen several cases of this kind in which the persons were dressed as women.

Dr. I. H. Hance mentioned a case in which Dr. McBurney had recently operated. By a plastic operation upon the male organ the person had been enabled to pass his urine in the erect posture. The sexual disposition of this person had varied according to the way he or she was dressed. When attired as a male the inclinations were those of a male and the reverse when dressed as a woman. Dr. McBurney had said he could not be certain whether the person was a male or a female. This hermaphrodite had a sister with exactly the same maladjustment of the genital organs.

Removal of the Tubes and Ovaries.—Dr. A. F. Currier showed several specimens, and described the cases, from a number of operations which he had recently done for the removal of the tubes and ovaries. Among these he mentioned a case in which the patient had shown decided evidences of tubal pregnancy. There was a history of profuse hæmorrhage. He had found a large tumor present. Another hæmorrhage was followed by collapse, the patient becoming unconscious and falling down stairs. The specimen presented was a hæmatoma and what had been thought by the speaker to be the remains of a tubal gestation sac. Examination had shown the presence of placental tissue. In one case the patient had had what had been diagnosticated as typhoid fever on the seventh day after the operation, but, after the attack had run a course, she had recovered. One patient from whom he had removed the sutures on the ninth day and had found a small abscess developed at the site of one of the sutures, had on the following day suffered a collapse, and he had been obliged to administer oxygen before she was out of danger. All the patients referred to had eventually done well.

Pregnancy complicated by Circumuterine Inflammatory Deposits.—This was the title of a paper by Dr. Ralph Waldo. He said there had been a time when he had thought that inflammatory deposits in the neighborhood of the uterus would in most instances prevent impregnation, and, if that was not the case, that abortion would occur in the early months of pregnancy. He then gave the histories of a number of cases illustrating the various phases of this problem. In looking over the histories of some of his cases, he had about decided that, while it was almost impossible for women with inflammatory products about the uterus to become pregnant, still many of them did so and some seemed to carry their children as if nothing was wrong. Others would abort a few times and then give birth to a child at term, while a third class would continue to abort during the whole of the child-bearing period. In carefully searching out a cause for this he had found that patients with inflammatory deposits about the uterus, who aborted habitually, in nearly every instance had the fundus of the organ bound by adhesions, and that the firmer it was fixed the more persistent were the abortions. He believed it to be of primary importance to ascertain the extent to which the body of the uterus was fixed before making a prognosis, for, if the body of the organ was immovable, and especially if it was retroflexed, he was of opinion that abortion would invariably result as long as the condition remained. On the other hand, there might be extensive deposits and adhesions about the lower part of the uterus, which might obstruct the passage of a child and which would still not cause the uterus to prematurely empty itself.

Dr. H. C. Coe said that it was not an uncommon thing to find conditions of old pelvic inflammation and the symptoms arising from them, and yet to have the woman go on to full term. The involvement of the tubes and ovaries was another thing. He should not expect a woman to go on to uneventful delivery if she had a well-developed salpingitis, with both ovaries prolapsed and fixed; still the adhesions did seem to stretch. The recognition of these circumuterine inflammations would be very difficult during pregnancy, and he did not know how one would go to work to treat such a condition at such a time.

Dr. Crook said that in cases where abortion occurred in the presence of these adhesions he had been inclined to refer the accident to a condition of endometritis rather than to the adhesions.

Dr. Currier thought that Dr. Waldo had made an important distinction in referring to adhesions at the fundus. They all knew of cases in which perimetritic inflammation had existed prior to pregnancy, and the patient had gone on to full term uninterruptedly. They had also heard of cases of well-marked tubal or ovarian disease in which pregnancy had continued to term. But he could not understand how this could be expected when the adhesions were attached to the fundus. It was hard to realize the immense amount of resistance which these adhesions offered. The endometritis was largely due to the irritation set up by the adhesions, and in the absence of these products of inflammation the endometritis alone would not cause abortion. He did not like the term "habit"; the body or its organs had no habits. This term and the word idiopathic should be expunged as applied to a departure from a physiological condition.

Dr. Grace Peckham said that gynæcologists recognized the fact that a general softening of the tissues took place in these perimetritic inflammations, and that they gave less trouble than might be expected. Still, the speaker was aware that the idea was prevalent that these adhesions would cause abortion or sterility. She was glad to indorse the opinion of the gentleman who had referred to a condition of endometritis as being a more frequent cause of the mishap.

The Chairman said that where there existed posterior adhesions, mentioned by the writer of the paper as prone to cause abortion at three months, it was certain that they would have to rise with the uterus or the fundus must become incarcerated. It was a question whether the adhesions themselves gave rise to the trouble or simply whether they did not give way soon enough and thus caused the uterus to empty itself; for, in the event of incarceration and development in the cavity of the pelvis, the uterus would have to throw off its contents. A woman was less likely to become pregnant when suffering from endometritis than to abort as the result of it.

Dr. R. A. Murray said he thought if these circumuterine adhesions were recognized early enough they could, by instituting proper treatment, be made to stretch. Any existing endometritis might also be sufficiently treated to allow of the woman going on to full term. It was often quite difficult, however, to say whether these women were really pregnant or whether the enlargement was due to the inflammatory products.

Exploratory Puncture of the Female Pelvic Organs.—Dr. George M. Edebohls read a paper with this title. He said that the scope of his paper did not embrace the subject of the diagnosis of the larger tumors of the abdomen, whether originating from the pelvic or abdominal organs, but concerned itself solely with the differential diagnosis of slight enlargements or masses, which were either situated entirely within the pelvis proper, or originated there, projected but slightly above the brim of the true pelvis into the abdomen, and which were recognizable only by combined abdominal and vaginal touch. As an aid in the differential diagnosis of these smaller tumors or masses, he had systematically practiced for two years past a method of exploratory puncture of the female pelvic organs which he had ventured to designate "abdominal puncture guided by combined vaginal and rectal touch."

The method as practiced was as follows: The skin of the lower part of the abdomen was disinfected as carefully as if laparotomy were contemplated. The middle finger of the left

hand was passed into the rectum, the index finger of the same hand into the vagina, the ovary, tube, small tumor or mass to be punctured being located by the fingers. The rectal finger, if possible, reached around behind to the upper limits of the mass, the vaginal finger being applied to its lower pole. By combined palpation a point on the anterior abdominal wall, directly over the center of the mass to be punctured, was located by the carefully disinfected fingers of the right hand. At this point the sterilized needle was carried perpendicularly through the abdominal wall and all intervening tissues and organs into the center of the mass. The fingers in the vagina and rectum fixed the diseased structures, controlled the course of the needle, and guided it into that part of the mass it was desired to puncture. An assistant then drew the piston, while the operator's right hand firmly grasped the barrel of the syringe, thus steadying it and the needle. The armamentarium consisted of a syringe of a capacity of two drachms and an exploring needle two inches and three quarters long from shoulder to point. The diameter of this needle must not exceed No. 15 steel wire gauge. The method was only applied when a full and entirely satisfactory diagnosis could be reached without it. Abdominal exploratory puncture, guided by combined vaginal and rectal touch, as compared with vaginal puncture or with abdominal puncture as usually practiced, possessed the same superiority that was usually conceded to bimanual palpation as compared with either the vaginal touch or the abdominal touch singly.

He had practiced the method in over seventy cases without the least untoward result. The guarantees of safety to his mind were: (1) *Perfect* asepsis, (2) immobility of the syringe and needle, and (3) resistance of the temptation to bore about in the tissues with the needle.

In thirteen out of fourteen cases in which he had removed the appendages, on one or both sides, for pyosalpinx and ovarian abscess, single or combined, he had been able, by exploratory puncture previous to operation, to prove the presence of pus and the futility of any other treatment than by laparotomy. In a case of very small abscess of the right ovary, with normal tubes and left ovary, the objective signs had been so slight, almost indiscernible, that he would have refused to perform a necessary laparotomy, if exploratory puncture had not fortunately revealed pus. In a case in which aortic stenosis and a small tubo ovarian abscess of the right side had coexisted, and the patient had nearly died on the table on the occasion of an examination under chloroform, he would have emphatically declined to perform laparotomy unless positively assured by exploratory puncture of the presence of pus.

In three cases of hæmatosalpinx—one of them a probable early tubal pregnancy—he had been able to make the diagnosis by exploratory puncture, and, as a result, to avoid three unnecessary laparotomies. In a case of tubal pregnancy, in the eighth or ninth week, exploratory puncture, by demonstrating the presence of blood free in the peritoneal cavity, had furnished positive proof that rupture had taken place, the diagnosis being confirmed by abdominal section.

In a case of hydrosalpinx or small cystoma he had made the diagnosis by exploratory puncture and had declined to perform laparotomy.

In one case exploratory puncture had confirmed a probable diagnosis of parovarian cystoma.

In a case of fibroma uteri, exploratory puncture, by proving coexistent disease of the appendages, had decided a question of practical therapeutics, the choice lying between electricity and salpingo-oophorectomy.

In a case of tubal and peritoneal tuberculosis, exploratory puncture had furnished evidence contributory to a correct diagnosis.

In one case exploratory puncture had enabled him to diagnosticate the carcinomatous character of a small tumor involving the posterior wall of the caput coli, the appendix vermiformis, and the right ovary.

Exploratory puncture had in several instances taken the place of an exploratory laparotomy and rendered it unnecessary.

In conclusion, he would add, as a word of caution, that exploratory puncture, guided by combined vaginal and rectal touch, as here delineated, aspired to the dignity of a somewhat exact and scientific procedure. A *sine qua non* of its safe and successful employment was the possession of a fair degree of skill and experience in bimanual palpation of the female pelvic organs. He would therefore urge that the method be attempted only by those whose tactile sense was sufficiently educated by daily practice to enable them to apply it with the greatest probability of attaining good and of avoiding mischief.

The discussion of this paper was postponed till the next meeting of the Section.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

THERAPEUTIC PRINCIPLES GOVERNING THE SELECTION OF CARDIAC MEDICAMENTS.

TWO LECTURES DELIVERED IN THE COURSE ON THERAPEUTICS AT THE MEDICAL DEPARTMENT OF DARTMOUTH COLLEGE.
October, 1890.

BY SOLOMON SOLIS-COHEN, A. M., M. D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS, PHILADELPHIA POLYCLINIC; VISITING PHYSICIAN TO, AND LECTURER ON CLINICAL MEDICINE AT, THE PHILADELPHIA HOSPITAL, ETC.

LECTURE II.

GENTLEMEN: We will to-day endeavor to apply the knowledge we have gained of the principles which underlie the mechanism of circulation, and of the relations between circulation and other functions, together with the knowledge we have gained of the pathological conditions which may affect the circulatory mechanism, and of the powers over that mechanism possessed by therapeutic agencies—we will to-day endeavor to apply this knowledge to the study of the proper method of treatment of certain chronic diseases and disorders of the heart. Our limited time compels us to cover almost too much ground for a single lecture, while it likewise forbids elaborate consideration of all the topics that might be included in this study. We must select a few types and study these carefully. The principles thus learned will be easy of extended application in cases fundamentally related with these types, but varying in details.

Here, as elsewhere, our *therapeutic diagnosis*, which must be based on *comprehensive clinical diagnosis* and on *accurate pathological diagnosis*, is represented by a triangle. The base line is a definite determination of *what* we are to do; the second side is a definite determination of *how* we can best do it; the third side is a definite determination of *where* the remedy may be best applied, so that the *what* and *how* may be accomplished.

These three lines being drawn, the included surface represents our remedy, and we must find agencies to fill its measure. But dropping metaphor, which, if carried too far, becomes unmanageable and misleading, it is only after we have reached a positive determination of the *what* and the *how* and the *where* that the therapeutic *which* comes up as a question to be answered.

In other words, we must determine what properties ought to be possessed by the remedy which we are to use before we can intelligently select from among those known to us the agent, measure, or combination most nearly fulfilling the conditions.

But, as the concrete may be grasped more readily than the abstract, let me make this clearer by means of an example.

Let us take as the simplest example at command a case of simple dilatation of the heart without valvular lesion. With the symptoms of this condition you are familiar. In the natural order of studies they come first. It was the palpitation, dyspnœa, coldness of extremities, tendency to vertigo and syncope, incapability for exertion, weak, rapid, irregular, perhaps intermittent pulse, œdema more or less marked, that, together with the physical signs obtained upon auscultation and percussion, led to the diagnosis. Embarrassment of circulation due to an incompetent heart was the clinical diagnosis. Dilatation without valvular lesion was the pathological diagnosis. Simple dilatation, it is true, is very rarely, indeed some say never, encountered at autopsies. Still it is a condition precedent to some of the lesions ordinarily found post mortem; it is clinically recognizable, and it affords the best foundation for our studies. The cause of the morbid condition in this case is in the background. It may have passed away, but it has produced its effect, and that effect is, in the strict use of words, incurable. We can not by therapeutic measures restore the heart to its normal size. The indications, then, are to prolong life and promote comfort.

Here we draw the base line of our triangle. The "*what* to do" is to place this patient's permanently damaged heart in such relations with his other organs, and the patient himself in such relations with his environment, that life may go on as long as possible and with as little distress as possible.

The "*how* to do it" is the next point to be determined. Evidently there are two complementary indications. The one is to reduce as much as possible the work placed upon the heart—*indirect restoration of equilibrium*. The other—*direct restoration of equilibrium*—is to strengthen the heart as much as possible, and to so regulate its action as to get the best possible results from what strength it possesses; in other words, the maximum of product with the least expenditure of energy.

Then the "*where*" naturally follows; first we apply our remedial measures to the organism as a whole, and secondly to the heart.

The first thing to be done is to place the patient in as favorable a condition as possible in relation with his environment. We must reduce the activities of the body at large to the level of the impaired power of the heart, and therefore the patient must not be allowed to pursue a laborious occupation, or one which may make sudden demands for extraordinary exertion, either mental or physical. He must be protected from shocks and emotional disturbances of all kinds. This is always difficult and sometimes impossible of accomplishment. Still we must make the effort. And here a very delicate problem is to be solved. We must caution the patient against undue exertion or excitement, but must do it tactfully, lest we ourselves, by the manner of our caution, cause shock, and thus steer directly upon Charybdis while warning against Scylla. I know of a case in which the physician's unguarded announcement of "heart disease" directly accelerated the death of the patient.

According to the degree of dilatation, the patient's social status and previous habits of life, and the extent to which untoward symptoms have developed, the physician's advice as to occupation, rest, and exercise will vary. Absolute rest may be necessary for a while, if there be acute or severe symptoms of embarrassment of circulation or res-

piration, or if there be much dropsy. On the other hand, a certain amount of exercise—active or passive, or both—is necessary, whenever no counterindication exists. It is necessary in order that terminal circulation and internal respiration shall be kept up, in order that the products of waste shall be removed. It must be gentle and intermittent; never allowed to become fatiguing. Walking is the best form of active exercise, and this may be supplemented by such passive exercise as the simpler and gentler forms of massage—friction and stroking. A wealthy patient may be told to take short walks while his carriage follows him, with instructions to enter the carriage as soon as he has gone the prescribed distance, or sooner, should he feel the slightest indication or premonition of fatigue. In the city, patients who do not have carriages should walk on a street in which there is a car-track, and in the opposite direction to the cars, so that they may ride home, and be able to do this at any moment. Where this is impracticable the walk must be so divided that going and returning shall not be too much. In all cases the distance must be prescribed and not left to whim; at first very little—half a block, in the city—and gradually increased to whatever maximum may be judged to be proper. This maximum must always be a little short of what is deemed to be the limit of the patient's ability. It is always well if a walk can be broken by intervals of sitting. We can for this purpose let patients ride to a park or square, if in the city, so that in the square they may alternately walk for little whiles, and rest for little whiles on the benches. Massage should be employed as an adjuvant when walking is possible, and as a substitute for active exercise when the latter is impossible. It should not be practiced more than fifteen or twenty minutes at a time, except in special cases. It must be gently and skillfully done, the patient being in the recumbent posture. The lower extremities especially should be manipulated. As far as is wise in any individual case, the effort should be made to act upon the veins directly, so as to impel the blood centripetally, yet not in too great a volume for the heart to deal with. The principles set forth in our study of massage must be kept in mind. Should dropsy be present, the time and manner of manipulation would be governed accordingly. Electric applications are of service in some cases of dropsy, but the consideration of this measure must be postponed until we have studied the action of the electric current more in detail.

In some cases the patient will be able and may be permitted to engage in some light occupation which itself allows opportunities for moderate exercise, alternating with rest. In these cases no special walks will have to be advised and massage may not be needed. It is necessary to secure for all patients, however, a certain amount of time in the open air every fair day, during which they may sit, ride, or walk, according to circumstances. Where a sufficiency of outing can not be obtained, inhalations of oxygen or of compressed air may be administered. Compressed air is also of advantage in equalizing the circulation by its mechanical pressure-effects. This subject, however, will be considered more fully in another connection.

Still treating of the subject of environment, the effort should be made to occupy the patient's mind in a pleasant manner, so as to keep his attention from his symptoms as far as advisable or possible. All of his senses should be agreeably entertained, without undue excitement. The sense of taste must be especially consulted, in order that small amounts of the best-chosen foods shall be found satisfying. In the matter of food we pass from extrinsic harmony—harmony with environment—to intrinsic harmony—balance of function.

The first effect of impaired cardiac power is deficient circulation. As we have lowered the general muscular and mental activities—that is, exertions in relation with external environment—to the level of this impaired circulation, so must we lower what may be called the internal exertions to the same level.

Beginning our consideration of these with the digestive system, it is obvious that we must reduce the amount of work placed upon it, while at the same time the impoverished condition of the heart-muscle calls for the best possible nutrition. And not only must we endeavor to nourish the heart itself, but we must remember that, as a further consequence of impaired circulation all the organs and tissues have suffered in two ways—from lack of proper material for anabolism, and from defective removal of the products of catabolism. The blood is, to a greater or less degree, stagnating in the veins. It can not get back to the lungs to be purified. So that the comparatively empty arteries bring little new material for upbuilding; the overfilled veins retain the poisonous products of the breaking down of tissue. Therefore, while diminishing the quantity of food ingested, in order thus to diminish the work of the digestive organs, we must highly increase the nutritive value of the food as well as its force-producing value, and, as far as possible, diminish the amount of waste that will be left to deal with. Such foods then are to be chosen as, in our study of the subject of food, were found to fulfill the indications mentioned—milk, oils and fats, especially butter, a moderate amount of properly prepared meat, eggs, fish, rice, grapes and certain other fruits containing sugar, malt preparations, alcohol (malt liquors, sweet wines, and spirits) in moderation, and the green vegetables. Potatoes and other bulky foods are to be interdicted, as are all sorts of indigestible cookery. Predigested foods, especially preparations of peptonized beef, and such combinations of peptone and maltose as the "peptonized milk-gruel," are of great service. The digestive ferments are sometimes serviceable, as is also the administration of dilute acids, during or immediately after meals. According to circumstances, food may be taken frequently in small quantities, or in the ordinary manner of three stated meals. As a rule, a glass of hot milk or milk-punch should be taken at bed-time.

Respiration, being the "second digestion," must be properly performed. We have already spoken of exercise and of inhalations of compressed air and of oxygen. Solution of hydrogen dioxide in water or in ether (ozonic ether) may be given to supplement respiration by utilizing the stomach for the direct introduction of oxygen into the blood. The so-called "fifteen-volume" aqueous solution, properly

diluted, may be given in doses of from one to four fluid drachms. The ozonic ether may be given in doses of one fluid drachm, with an equal quantity of glycerin, in enough water to make a tablespoonful. These agents also tend to slow and strengthen the heart. The cardiac medicaments, to be considered later, likewise favorably influence the respiration.

Extraordinary attention must be paid to the excretions, not only for the reasons already and sufficiently dwelt upon, but also to prevent dropsy from accumulation of fluids in the ill-nourished veins—a combination of circumstances under which transudation is most likely to occur. Fortunately, among the medicaments most appropriate to the cardiac conditions are several of the best diuretics and diaphoretics. In addition to these, the consideration of which we will postpone for a moment, agents acting upon the liver and the intestines must be employed, continuously or from time to time, as indicated.

Three indications are to be fulfilled by cholagogue and purgative medication. First, we avoid increased obstruction to the great portal circulation, already sufficiently embarrassed. Secondly, we can, by the use of suitable agents, remove from the circulation, by way of the intestinal vessels, a large amount of fluid, thus diminishing the volume of blood to meet the impaired propulsive power of the heart, and increasing the comparative richness of the blood in corpuscular elements. In cases of dropsy we actively resort to this method in order to secure re absorption of the transuded fluid to take the place of that removed by way of the bowel; but it is better to prevent dropsy by continuous mild purgation. The third indication is that of removing waste products, the importance of which by this time we fully understand. Sodium phosphate, euonymin and similar resins, rhubarb, Epsom salts, Rochelle salts, various mineral waters, calomel, and jalap, are among the most useful agents, the choice depending upon principles already laid down in discussing cholagogue and purgative medication. Calomel and Rochelle salts have the additional usefulness of a certain amount of diuretic power. It is especially in cases of cardiac impairment that the diuretic properties of calomel are most available.

Remedies to improve the condition of the blood itself are also to be administered. These might have been discussed in connection with food, but perhaps are better emphasized by the separation. Of these, iron stands first; next to it is arsenic. Chloride of gold and sodium, bichloride of mercury, and chloride of calcium may sometimes be useful for short periods in alternation with iron or arsenic. The principles which apply here we have already discussed in our study of the blood. Cod-liver oil stands prominently forth as a hydrocarbonaceous food and a blood-former of great utility. Phosphorus and its preparations, more especially the hypophosphites, may in some cases be advantageously combined with the cod-liver oil. Given alone, they are of little use in the class of cases under consideration.

And now, having placed our patient in harmony with his environment; having lowered his digestive work to the capacity of his circulation, and improved both the digestive product and the blood itself in accordance with the needs of the impoverished tissues; having done what we could to improve respiration so far as it can be improved independently of circulation; and having duly attended to the excretions—we can devote our attention to the organ which is itself at fault.

The first lesson to be drawn from the considerations thus far passed in review is this: That the diseased organ is not the only organ to be treated, and not always the first; and that direct treatment is not always the first or the best. It is very probable that the measures already adopted will so far have improved the heart by their indirect influence as to considerably modify the indications for direct cardiac remedies.

While this is the preferable method of procedure, yet there is another side to the question. It may be that, on account of the patient's necessities or the demands of his business, our advice as to rest and regulated exercise can not be carried out. Remember, this is the best advice. It is our duty to place before the patient the danger of neglecting it. Still it may be impossible to follow it. Then we must modify it to the exigencies of the occasion, and the choice of a remedy to act directly upon the heart will come up at once.

In the case supposed of simple dilatation without valvular lesion, the indication is "to empty the veins and fill the arteries"; and the best agent at our command is digitalis. The best preparation of this drug to use in the case supposed is the powder of the leaves, which may be made into pill and given in the dose of from one fourth of a grain to one grain or more, three times a day. The tincture may be employed in doses of from two to five drops or more, three times a day. Where a diuretic effect is specially desired the infusion is sometimes to be preferred in doses of half a fluidounce, night and morning.

By prolonging the diastole, digitalis increases the period of comparative rest; of anabolism. It gives opportunity for increased nourishment of the muscular tissue. It gives opportunity for an increased accumulation of energy to be later discharged in the systole. And by increasing the force of the systole it compensates for a certain part of the lost original vigor of the heart. By slowing the circulation, it diminishes the relative expenditure of energy in a given time. By its action upon the kidney, it increases the excretion of urine—both the watery and the solid constituents.

It may, however, have one untoward effect. It heightens blood-pressure by causing contraction of the arterioles, and thus to a certain extent opposes the cardiac contraction. Should this action be too pronounced, we can overcome it by the simultaneous administration of nitroglycerin, or other nitrite, as already explained. The nitrites, by dilating the vessels, and especially the peripheral vessels, invite the blood into the capillary circulation, and take off from the heart a great portion of its labor. As a matter of course, they must be cautiously employed, the smallest dose (one one-hundredth of a minim or less of nitroglycerin, three times a day) being given at first, and the quantity gradually increased until the desired effect is produced. In

some cases nitroglycerin or nitrite of sodium may be given alone. The labor of the heart being thus diminished and its tone having been improved by nutritive measures, the administration of digitalis will not be necessary. This expedient is particularly useful in the treatment of fatty heart, in which digitalis, as we have previously seen, is, as a rule, counterindicated. In these cases arsenic and strychnine are extremely useful agents.

But to return to digitalis, we must remember what was emphasized in our special study of that drug—that no sudden change of posture is to be permitted during its administration. Especially dangerous is the change from recumbency to the erect posture. We must also avoid the risk of producing a cumulative effect—the nature and causes of which we have previously studied—and the best, as it is the most obvious, method to avoid this danger is the routine intermission of the use of the drug at intervals to be determined by all the circumstances of the individual case.

But what are we to substitute for digitalis during these periods of intermission, or in those cases in which it is not well borne, though apparently indicated? Of single agents, my own experience leads me to prefer strophanthus. Convallaria and adonis vernalis, or their active principles, and sparteine, a principle derived from scoparius, are also useful, and by some authors preferred. Better sometimes than any single agent is the combination of caffeine or cocaine with strychnine. Before discussing the other agents, then, let us briefly recall our knowledge of the action of caffeine and of that of strychnine, and see why it is that this combination is of such great utility. Strychnine, in the first place, is a general tonic, improving digestion and increasing the capacity of the individual for physical and mental exertion. In addition to this, it has distinct usefulness as an agent acting upon circulation and respiration. It affects the centers of organic life, heightening their impressionability and increasing the energy of their discharge. It thus acts by central influence as a stimulant to the heart and to the respiratory muscles. But it also acts peripherally upon the motor ganglia of the heart, directly stimulating and heightening the energy of their discharge. It also acts upon the muscular tissue itself, increasing the vigor of contraction, a fact of which we have abundant clinical evidence as to man, whatever may be the laboratory evidence as to animals. It is thus a catabolic agent; but the catabolism which it produces is an effective catabolism, giving the highest force-product with the least degree of waste. It has some tendency to heighten peripheral blood-pressure by contracting the vessels, but this is not always marked.

Caffeine, or perhaps we ought to say the article of commerce sold under the name of caffeine, but which, as Mayo has shown, is in reality a mixture of caffeine and theine—so-called caffeine, then, acts to some extent upon the nervous supply of the heart, but its chief action is upon the heart muscle. It increases very greatly the vigor of the systolic contractions and diminishes their frequency. It improves respiration both by directly strengthening the respiratory muscles, and indirectly by its action upon the circulation. It is a diuretic of no mean power. Like digitalis, caffeine raises the arterial tension, but in the case of caffeine this effect is not so likely to be excessive as it is in the case of digitalis; so that the conjoint use of the nitrites is not often necessary. A moderate elevation of arterial tension, if well distributed, is beneficial, as it secures a better distribution of the blood. In order to get the full benefit from caffeine it must be used in fairly large doses—five grains three times a day, for example. With this, from one sixtieth to one thirtieth of a grain of a strychnine salt may be combined. Where in an individual case, for any reason, a more rapid effect is desired than caffeine usually gives, we may have recourse to cocaine, which may be given *per os* in doses of from one eighth to one half of a grain, or hypodermically in doses not exceeding one fourth of a grain. For prolonged administration, however, caffeine is to be preferred. Where neither caffeine nor its combination with strychnine seems to be sufficiently stimulating—that is to say, where, despite the increased vigor of the cardiac contraction, it seems not to be sufficiently free—a minute dose of cocaine, say one sixteenth of a grain, may be advantageously combined with the other agents for continuous use for short periods, say a week or two at a time. In some cases, instead of adding cocaine to the pill, a good wine of coca may be given as a beverage in appropriate doses. The patient should also be advised, even while taking digitalis, to drink a cup of strong coffee at each meal and before going to bed. In a few cases of moderate impairment of cardiac vigor the drinking of strong coffee has sufficed to keep the patient comfortable, without resort to digitalis or other drug.

Now a few words as to *strophanthus*, which, as already said, I esteem more highly than any other agent yet brought forward to replace or supersede digitalis. This drug is not yet official, and it is difficult to get a reliable preparation. The tincture prepared according to the directions of Fraser, of Edinburgh, is the best. It may be given in doses of from one minim to ten, or in some cases, with due caution, even twenty minims, three times a day; or a large dose may be given at first and the impression maintained by small doses at shorter intervals. The duration of its effect gives to it much of its great usefulness. Its effects are similar to those of digitalis, in that it slows the rate of the heart, lengthens the interval between the contractions, and increases the vigor of the muscular action. This is thought to be due to direct action on the muscle substance, and not to any effect upon the nervous system. By its action on the heart it raises blood-pressure, producing diuresis. It does not, however, markedly contract the arterioles as does digitalis, and therefore compensatory use of the nitrites is not necessary. It does not disturb the digestive tract. A patient now under my care, in whom cardiac weakness is part of a general muscular and nervous degeneration, takes tincture of strophanthus and tincture of digitalis alternately and coincidently in the following manner: Having taken thrice daily for a week ten drops of the tincture of digitalis, he begins to diminish the quantity, substituting in each dose the first day a drop of the tincture of strophanthus for a drop of the tincture of digitalis. The second day two drops, the third day three drops are substituted; and thus during ten days the digi-

talis is diminished and the strophanthus increased *pari passu*, until finally the patient is taking ten drops of tincture of strophanthus and no digitalis. After a week of strophanthus he begins to substitute for it the digitalis, a drop at a time, reversing the previous process. This expedient has been found preferable in this particular case to either the uninterrupted continuance of either drug or an abrupt change from one to the other.

Strophantin, a glucoside derived from strophanthus, is given in doses of from $\frac{1}{120}$ to $\frac{1}{50}$ of a grain hypodermically, repeated at long intervals, perhaps of many days, as the effect is said to be quite prolonged. I have not yet acquired sufficient personal experience with the use of the glucoside to speak positively concerning it.

Convallaria and its glucoside, *convallamarin*, have received high encomiums from Sée and other authorities; but, as I stated when considering this drug, neither clinical experience nor laboratory studies warrant a decided expression of opinion in its favor. In some cases it is highly useful as a substitute for digitalis, but it frequently disappoints us. Its properties as a diuretic are more constant than its power over the heart. It may be that the uncertainty and disappointment I have experienced in the use of this drug are to be ascribed to imperfect preparations rather than to the drug itself.

Adonis vernalis and its glucoside, *adonidin*, have been found useful by so eminent a clinician and careful observer as Da Costa. My own experience with this drug is very limited, but is satisfactory as far as it has gone. It is similar in its action to digitalis both in its effects upon the heart and vessels and its diuretic properties; but is much more powerful, and its use is said not to be attended with risk of cumulative action. At present it is employed chiefly as an adjuvant to digitalis or a temporary substitute therefor, though it is said to succeed sometimes when digitalis fails. According to some authorities it is even more likely than is digitalis to produce symptoms of gastro-intestinal irritation (nausea, vomiting, and purgation). There is no official preparation of adonis. An infusion is made (one half to two drachms of the root to six fluidounces of water), of which the dose is half a fluidounce every two to four hours. Adonidin is given in doses of from an eighth of a grain to half a grain, repeated as necessary.

Sparteine, derived, you will remember, from broom, may be given (as *sparteine sulphate*) in doses of from one sixteenth of a grain to three or four grains, the ordinary range being from half a grain to two grains. It has received high encomiums both from experimenters and clinicians, and is recommended in the warmest terms by so practical an observer as Bartholow. Nevertheless, I must confess to my own frequent disappointment in its use, perhaps because I have not yet mastered the art of administering it. There is undoubtedly much in the art of administering remedies. As two painters will produce different effects with the same pigments—the inimitable glow of Turner's Venetian scenes, or the blush of shame that o'erspreads the skies of his copyists—so may two therapeutists produce different effects with the same drugs differently applied. I have, however, in some cases, found sparteine fully equal to my expectations. In these its most marked properties were a comparatively rapid action and a regulating power—that is, a power to render steady and continuous the previously unsteady and intermittent heart-beats—even superior to that of digitalis. In these cases the drug was given in small doses, repeated four or five times during the twenty-four hours. They were not, however, cases of simple dilatation such as we are now discussing, so that perhaps the conclusion is justifiable that the peculiar virtues of this drug are better applicable to the relief of those disordered conditions of innervation and muscular action which are manifest in the more advanced stages of valvular lesions. When effective, the action of the drug continues for twelve or twenty-four hours, and, according to some authorities, even longer. Sparteine has considerable diuretic power, though, as a diuretic simply, it is, in my experience, inferior to the infusion of broom. There is, however, this drawback to the use of bulky infusions in the treatment of cardiac disease—that the quantity of fluid ingested is likely to be disadvantageous.

Erythrophlœum is a drug which may eventually be found useful in the treatment of weak hearts; at present its use is almost exclusively confined to the laboratories.

Barium chloride has a limited degree of applicability, and I have had a few satisfactory results from its employment, more especially in the treatment of the overacting heart and relaxed vessels of exophthalmic goître, but, as was stated in discussing this agent, I can not advise you to resort to it until greater experience has been accumulated as to its exact range of usefulness.

We are now perhaps in a better position to illustrate by a further refinement the extended application of our therapeutic triangle, *what*, *how*, and *where*. As we used it in solving the main problem of the line of treatment, so we can, indeed must, however unconsciously, use it in solving special problems as to details of treatment. In the selection of a drug to act upon the heart we can choose one which affects principally the nerves, or one which affects principally the muscles, or one which acts upon both. Or, again, in its action upon the nerves a drug may slow the heart by depressing the motor apparatus—cerebral, peripheral, or communicating; or it may slow the heart by stimulating the inhibition apparatus—central, peripheral, or communicating. In Brunton's most admirable treatise, to which I again acknowledge my own great indebtedness, you will find suggestive data for the study of this phase of the subject. That which makes digitalis preferable in most cases to all the other drugs mentioned is the fact that it acts both on nerves and on muscle, both on inhibitory and motor apparatus, and that the result of this combined action is to slow and strengthen the heart, by a stimulating effect throughout, without depression of any kind. For the same reason the combination of caffeine and strychnine is useful. It is true that in studying digitalis we classed it among the cardiac sedatives as well as among cardiac tonics. But, as I then stated, its sedative power is the sedative power of strength; the irritation which it calms is either the irritation of weakness or the irritation of loss of con-

trol. Wood's article may profitably be consulted on this topic.

When sedation is required for a heart which is acting too rapidly or too powerfully, because it is too strong, digitalis is not an appropriate sedative. If I ask the class to mention the drug which, above all others, should be used to quiet an hypertrophied heart, you answer "*aconite.*"

In our study of aconite we recognized in it a depressant *ab initio.* Digitalis, if pushed too far, may paralyze by exhaustion. But aconite is a paralyzing agent from the first. It depresses nervous function without much interference with muscular power *per se.* While it is true that experiments on normal animals have not revealed any such property, I feel warranted in saying that its prolonged administration, in perfectly safe medicinal doses, seems, clinically, to cause a certain degree of retrograde metamorphosis in hypertrophied heart-muscles, probably by influence on trophic nerves, or, in other words, by interference with anabolism. Its peculiar field of usefulness is in cases where we wish to reduce power, and hypertrophy without valvular lesion may serve as a type of these cases.

In a case of eccentric hypertrophy due, we will say—as in the case of a blacksmith I have in mind—to excessive muscular exertion, the *what*, *how*, and *where* are self-evident.

We can not materially alter the condition of the heart-muscle. We must avert evil consequences by regulation of the patient's life and by the use of agents to diminish the force of the heart's action. Now, regulation of the patient's life does not imply that we are to increase his exercise up to the level of his heart's overaction. If we could by so doing increase the size of all his organs, including the skeleton, proportionately—in other words, if, having a gigantic heart to deal with, we could, by prescribing giant's work, transform the patient into a Goliath—that would be the proper line of treatment; but this is manifestly impossible. Even the heart itself is not the subject of regular and proportionate enlargement; the left ventricle, in the case we are considering, being disproportionately increased both in capacity and in the thickness of its walls. We must, therefore, paradoxical as it seems, prescribe rest. It is not necessary in the ordinary case—that of the blacksmith whom I have mentioned, or that of athletes, a class of men who frequently suffer from a similar condition—to prescribe absolute rest in bed, except in the presence of urgent symptoms. We must, however, at once interdict the overexertion which has brought about the morbid condition. Furthermore, while permitting sensible exercise, we must not allow it to be too prolonged; and all sudden or violent exertion must be absolutely prohibited. Alcohol, tobacco, immoderate eating, and mental excitement must be avoided. To prevent straining at stool, the diet must contain laxative elements, and an occasional mild purge be exhibited. All conditions which tend to disturb the circulation, particularly in the abdomen and in the lungs, must be guarded against.

The quantity of fluid taken into the stomach should be limited. In the presence of symptoms of cerebral hyperæmia a hydragogue cathartic may be used to unload the vessels. A blister may be applied to the nape of the neck, and wet cupping of the chest, or even venesection, may be performed in urgent cases. As a rule, however, rest and the administration of aconite will avoid necessity for bleeding. The dose of the tincture of aconite root will vary from one to five drops, which may be given three times a day or at intervals of two or three hours according to circumstances. Sometimes it is well to begin with larger doses, and as the influence of the drug becomes manifest to diminish the dose to as little as will keep up the effect. Very often one drop twice a day will be efficient. In some cases, however, comparatively large doses will need to be continued, or at all events to be resorted to, from time to time, for five or six days together. Diluted hydrocyanic acid in doses of from two to five drops, diluted hydrobromic acid in doses of from ten to thirty minims, potassium bromide in doses of from ten to thirty grains, potassium iodide or sodium iodide in doses of from five to ten grains, may be used as adjuvants to the aconite, or in its place. Belladonna has been recommended. I have no experience in its use in this connection, for to my mind it seems counterindicated, its action, as we have seen, being both to increase the rapidity and the vigor of the heart's action and to raise the arterial tension, except when the opposite effect results from paralysis by exhaustion due to large doses.

There is, however, one condition of overaction of the heart in which belladonna is of considerable service—namely, in the irritable, irregular, and feebly overacting heart of some cases of tobacco poisoning. In this condition the combination of belladonna (which is in these cases preferable, by reason of its antispasmodic properties, to its alkaloid, atropine) with strychnine, digitalis, or caffeine has in my hands proved useful.

The difference between this condition and the condition of excessive strength we have been considering is at once rendered evident by the fact that digitalis has been enumerated as among the agents usefully combined with the atropine. Diluted hydrocyanic acid, cimicifuga, musk, the bromides, and especially monobromated camphor, often act beneficially in this disorder. Sodium iodide in small doses is also useful.

Having firmly fixed in our minds, then, the principles which should guide us, and the measures which may be most usefully applied in the treatment of dilatation with weakness, and hypertrophy with excessive power, apart from valvular lesion, and having briefly alluded to the pseudo-hypertrophy of irritation by tobacco, we have now to consider how our treatment is to be modified when either of these conditions coexists with a valvular lesion. We can do this more briefly on account of the wide range which our previous studies have taken. It will be self-evident that where hypertrophy coexists with a valvular lesion, being itself not alone the physical result of that valvular lesion, but also Nature's "spontaneous healing," in the sense in which we have agreed to use this term, it will be self-evident that where such hypertrophy is in degree merely enough to compensate for the damaged condition of the valve there is no occasion for therapeutic interference. Conversely, when a valvular lesion has been thus compensated by hypertrophy, the condition of the valve

affords no indication for therapeutic interference. Should the hypertrophy be excessive—that is, more than sufficient for compensation—just in the degree that excess exists will such excess afford indication for treatment with aconite or a bromine salt, or both. In the majority of cases, however, even when the lesion—for example, mitral regurgitation—is compensated by ventricular hypertrophy, it is necessary to adopt, to some extent, the hygienic measures which we discussed at length in the case of simple dilatation, for the hypertrophy which balances mitral regurgitation is to be looked upon as potentially a condition of dilatation. It becomes actual dilatation when it no longer suffices to overcome the obstruction to circulation brought about by the regurgitation. This is called *rupture of compensation*, and the treatment then is almost exactly that of dilatation, both hygienically and medicinally. In other words, in cases of mitral regurgitation the main indication for treatment is afforded not by the condition of the valve, but by the condition of the muscle relatively to the valve. Clinically, the rational symptoms—that is to say, the condition of the circulation and respiration, the presence or absence of dropsies—are the data upon which we base our opinion as to whether or not compensation exists.

Somewhat different indications are afforded by aortic stenosis, for here not alone the condition of the muscle, but that of the valve itself must be considered when the selection of medicaments becomes necessary—that is to say, when compensation has been ruptured. For example, we can not resort to digitalis to strengthen the muscle, as we would in a case of mitral regurgitation with ruptured compensation, on the principle that the condition is practically a condition of excessive dilatation. Digitalis, as we have seen, raises peripheral blood-pressure, and would thus cooperate with the obstruction at the aortic orifice in opposing exit of blood from the ventricle. By lengthening the diastole, it would permit a quantity of blood to enter the ventricle beyond the capacity of the ventricle to empty itself, thus increasing the embarrassment. If regurgitation coexists with the stenosis, as is usually the case, the lengthening of the diastole would also permit a greater reflux from the aorta into the ventricle. The net result, then, of the action of digitalis in aortic stenosis would be to overfill the ventricle, and any increase of power of contraction which it would give might tend to drive the blood backward through the mitral orifice, rather than forward through the obstructed aortic orifice; for it would be quite possible for the gradual increase in the size of the heart, which has been brought about by the lesion, to have rendered even an intact mitral valve relatively incompetent and not able to withstand any great strain. Blood, like everything else, moves in the direction of least resistance.

If now we apply our therapeutic triangle, we see that *what* we want to do is to get the blood out of the ventricle as quickly as possible, and to have the ventricle again moderately refilled as quickly as possible. *How* to do this is to increase the rapidity of the contractions and to diminish the intervals between them. A moderate degree of increased vigor is, of course, necessary in order to overcome the obstruction; and, further, systemic blood-pressure should be lowered as far as is consistent with movement of the blood into the veins. These conditions are fulfilled by using a combination of atropine and strychnine, in conjunction with nitroglycerin or nitrite of amyl. The atropine, in addition to its power to hasten the rate and increase the vigor of the cardiac contractions, is, like strychnine, a stimulant to respiration also, while the nitroglycerin keeps the arterial tension within the required limits. The truth of this theory was abundantly demonstrated to me by a case under my care at the Philadelphia Hospital last winter, which I have recorded in detail in the forthcoming volume of the *Philadelphia Hospital Reports*. In this case mitral regurgitation coexisted with aortic stenosis, and the rapid amelioration of symptoms which took place under treatment was quite gratifying. A pill, containing one sixtieth of a grain of atropine sulphate and one thirtieth of a grain of strychnine sulphate, was given three times daily, and nitrite of amyl was given in doses of five minims, dissolved in a fluidrachm of alcohol, every three to four hours as necessary.

In cases of mitral stenosis—that is to say, when the flow of blood from the left auricle into the left ventricle is impeded—the indications are (1) to prolong the ventricular diastole so that as much blood as possible may get through the narrowed orifice; (2) to strengthen the heart muscle so that the auricular contraction may be as effective as possible; and (3) when this lesion coexists, as it often does, with mitral regurgitation, to lower peripheral blood-pressure. The hygienic measures already discussed—iron and arsenic as nutritives, strychnine and caffeine as cardiac tonics—fulfill the two indications of uncomplicated stenosis, while digitalis and the nitrites are useful in cases complicated with regurgitation.

Aortic regurgitation remains to be considered, for uncomplicated tricuspid lesions and lesions of the pulmonary valve are very rare, and it will not be worth while to consume any of the brief time left to us in their discussion.

There has been much difference of opinion as to whether or not digitalis should be used in cases of aortic regurgitation. As has been more especially pointed out by Bartholow, the rational symptoms rather than the pathological condition must be our guide. It will be easily seen that undue prolongation of the diastole will permit greater regurgitation, and that when compensation can be brought about without digitalis this drug had better be omitted. Nevertheless, the increased force which results from the digitalis action may be sufficient to more than balance the increased regurgitation which it permits, and in many cases it proves useful. It is, as will be readily evident upon reflection, most efficient in those cases of aortic regurgitation which coexist with mitral disease. My advice, then, would be, in any case of aortic regurgitation, to postpone the use of digitalis until other measures have proved inefficient. The most useful combination of medicaments which I have employed is that of atropine, strychnine, and caffeine, with the occasional use of the nitrites. The principles which dictate this combination you have already been sufficiently familiarized with. In all cases, of course, those measures of hygiene which bring the patient into harmony with

his environment, and which aid in restoring the internal balance of function independently of the medicaments, are to be as carefully prescribed as in the case in which we considered such measures at length.

There are other measures than those mentioned which might have been considered had time permitted. The effects of heat and cold, the use of opium as a sedative and as a heart-tonic in small doses, might have been enlarged upon. Camphor, and especially the monobromated camphor, musk, ergot, cimicifuga, veratrum viride, and other drugs which have a certain usefulness in special conditions, deserve more than mere mention. But we have had to choose the best and the most generally applicable measures; and then, too, we have alluded to the virtues of these agents in our previous studies. What I most regret is our inability to make a special study of so-called cardiac asthma, and of the measures which more particularly improve the pulmonary circulation. But with some reflection the principles we have applied to the relief of the systemic circulation may be applied to the pulmonary circulation also. Indeed, as both suffer together, both must be relieved together.

I will only say further in this connection that I believe venesection would frequently relieve a laboring right heart, and should be resorted to more than I have as yet dared to do. Hydragogue purgation, wet-cupping, dry-cupping, counter-irritation, the use of the nitrites, are among the most efficient measures at our command.

In conclusion, then, the first problem which presents itself in the treatment of chronic diseases of the heart is to determine whether or not Nature herself has brought about restoration of equilibrium. Where this is the case, the function of the therapeutist is so to guide the life of his patient as to postpone to the furthest time possible the rupture of compensation. When compensation has been ruptured, or in cases where it has never been established, the first duty of the physician—unless urgent symptoms, such as ascites or thoracic effusions, call for immediate measures to meet the emergency—is to institute those hygienic measures which shall restore extrinsic and intrinsic harmony. After this, if medicaments are necessary, their selection should be based upon a careful study of all the conditions of the individual case, taking due account of the mental and physical characteristics of the patient.

Hernia of the Falloppian Tube.—"At the Leipsic Obstetrical Society, Dr. von Tischendorf read notes of an interesting case of femoral salpingocele. The patient was an elderly woman, with symptoms of strangulated femoral hernia. The sac appeared, before operation, to contain omentum. When opened, no omentum was found, but the left Falloppian tube much enlarged on account of œdema. It bore, close to the ostium, a prominence of the size of a cherry, caused by dilatation of its walls. This prominence fitted into a corresponding depression in the hernial sac. Both tubes and sac were removed; recovery was uninterrupted. Dr. von Tischendorf could only find four cases of the kind reported in medical literature, and of these, two occurred many years since."—*British Medical Journal.*

A Test for Fæcal Matter in Water.—Paradiazobenzolsulphuric acid made feebly alkaline in a twenty-per-cent. solution will, when added to water which is contaminated with fæcal matter, show a yellowish coloration within five minutes.—*British and Colonial Druggist.*

Original Communications.

A SUBMEMBRANOUS LOCAL TREATMENT OF PHARYNGEAL DIPHTHERIA.

By A. SEIBERT, M. D.,
PROFESSOR OF DISEASES OF CHILDREN, NEW YORK POLYCLINIC, AND PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN DISPENSARY.

Primarily the diphtheric process is a local disease. It is caused by the invasion of bacteria into the mucous membrane of the respiratory tract, which produces an inflammation of the invaded region. It is now conceded by most bacteriologists that in the majority of cases of diphtheria the bacillus found by Klebs and Loeffler is the chief cause of this disturbance. Inoculations of cultures of this bacillus upon guinea-pigs and rabbits, as well as bacteriological research by clinicians like Heubner, leave little doubt in this direction.

Yet other pathogenic germs besides this one may enter the mucous membrane in company with the Loeffler bacillus in a large proportion of cases, thus causing clinical pictures varying as to the aspect of the membrane produced, as well as to the extent, more or less pernicious character, and duration of the diphtheric invasion. If from a purely practical standpoint one might venture to suggest an idea not exclusively belonging to clinical experience, I should say that to my mind these varying pictures of the diphtheritic process in different cases (though often observed in the same epidemics, at the same time, and in members of the same families) were caused by the *different proportions* of these different kinds of bacteria, entering the mucosa at the same time, so that where other pathogenic germs than the true diphtheria bacillus of Loeffler were in the majority, this most pernicious micro-organism did not find the surroundings favorable enough for a full development of its growth, and was curtailed in its action on the human tissue by this fight for place, so as to only result in more or less milder forms of diphtheria. At all events, we at the present time, mindful of the works of Oertel, Brieger and Fraenkel, and others, may logically assume that the more bacilli of Loeffler are found in a given case of diphtheria, the more fatal its prognosis, and the smaller the quantity of these germs in a case, the milder its form.

Roux and Yersin have again called attention to a pseudo-bacillus of diphtheria, having no virulence, but otherwise very much like the true germ, which appears to become virulent when associated with Fehleisen's coccus of erysipelas. If this can be so, then other bacteria may have the power to decrease the virulence of others.

The changes brought about in the tissues of mucous membranes by the invasion of the bacteria causing diphtheria have been elaborately demonstrated by Oertel in his great atlas. The histology of the pseudo-membrane proper has found a most careful student and explicit demonstrator in Heubner. He has examined the pseudo-membrane in cases from five hours to six days old, and his results have thrown considerable light on the diphtheritic process. In a drawing from Heubner's work, showing the normal conditions of the epithelial layers of the tonsillar

mucosa of a child (Fig. 1), we find the upper layer to consist of flat, horny, the middle of round, and the lower

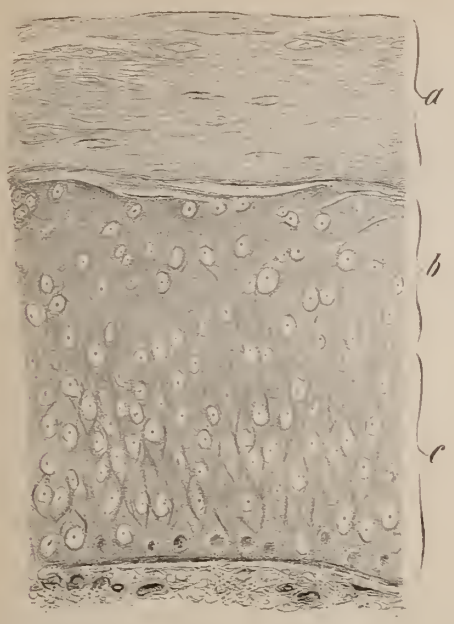


FIG. 1.—*a*, upper epithelial layer; *b*, middle epithelial layer; *c*, lower epithelial layer; below, the connective-tissue layer of the mucosa.

stratum of oval-shaped epithelial cells, below which last we notice large round cells, connective tissue, and blood-vessels. Heubner found that even the first noticeable trace of the diphtheritic pseudo-membrane (taken from the tonsil five hours after the beginning of the attack) consisted of an exudate coming from *the inflamed blood-vessels*, which after wandering upward with the numerous leucocytes (white blood-corpuscles) between the oval and round cells of the epithelium, lodged between the horny upper cells and there coagulates, imbedding within it numerous bacteria. This stream of exuding fibrin, from below upward, keeps on steadily as long as the action of the bacteria upon the blood-vessels and their surrounding tissue progresses, ultimately resulting in all the epithelial layers being permeated, distended, and infiltrated by this coagulated fibrin, so that (as

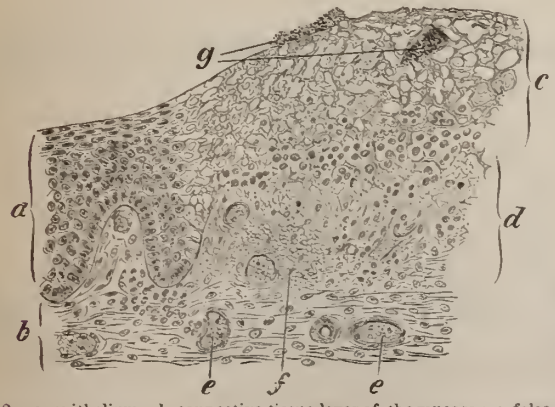

FIG. 2.—*a*, epithelium; *b*, connective-tissue layer of the mucosa; *c*, false membrane; *d*, infiltrated lower epithelium; *e*, blood-vessels; *f*, extravasated blood.

Heubner has it) while in the beginning of a case the exudate is imbedded between the epithelium, in advanced cases the epithelium (or what is left of it) is imbedded in the exudate (Fig. 2, taken from Ziegler's *Pathological Anatomy*).

The practical lesson we may learn from these facts is that the appearance of the pseudo-membrane is the sure sign of bacterial action upon the *lower* layers of the mucosa, directly below this sign of this invasion.

All investigators unite in stating that far more bacteria are found in the epithelium and the pseudo-membrane than in the tissue below. No doubt many of the active bacteria are carried away by the circulation after penetrating the blood-vessels, and others are carried upward with the flowing exudate, to be imbedded in the coagulated mass at the periphera.

L. Brieger and C. Fraenkel have lately demonstrated the chemical body produced by the action of the Klebs-Loeffler bacillus upon the albumin of the pseudo-membrane, which getting into the circulation produces the different varieties of diphtheric paralysis. This ptomaine, called by these authors "toxalbumin" of diphtheria, is produced in but small quantities in the early stages of each case, but the larger and older the diphtheric area, the more toxalbumin is produced. Injected into the circulation of animals, this toxalbumin invariably produces paralysis.

The conclusions as to the treatment of diphtheric patients we may logically draw from these facts are:

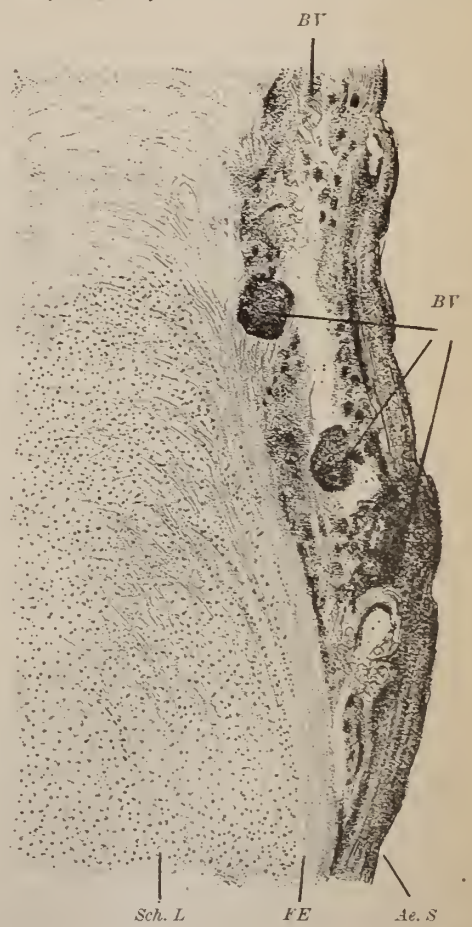

FIG. 3.—*Ae. S*, eschar from nitrate of silver; *FE*, *Sch. L*, infiltrated mucosa; *BV*, bacteria.

1. The pseudo-membrane is an exudate coagulated in the epithelium coming from the deeper layer of the mucous membrane, and therefore not the disease, but the result of it.

2. Hence all treatment attempting to dissolve or to forcibly take away this pseudo-membrane *is to no purpose*, as it does not in the least affect the diphtherically inflamed parts.

3. All medicines given by the mouth for the purpose of entering the invaded region of the mucosa are of no use whatsoever in this direction, as they can not possibly penetrate the coagulated fibrin and swollen epithelium to reach the bacteria producing this affection.

4. All local applications of strong caustics—as the galvano-cautery, nitrate of silver, etc.—are of no avail, as the diphtheric germs are far beneath the reach of these agents (Fig. 3, action of nitrate of silver upon diphtheric mucosa. Oertel, Plate No. XVI).

Tests of Loeffler and others have shown that the bacteria causing diphtheria can not be destroyed at all by weak antiseptic solutions. The bichloride of mercury, for instance, given internally, dissolved in 10,000 parts of water, could not destroy this bacillus even if it were completely surrounded by it. Given as it is in teaspoonful doses by the mouth, it passes gently over the pseudo-membrane into the stomach of the patient, from there into the circulation, and the little of it that may come in contact with the bacilli in the diseased mucous membrane can possibly be of no account in even retarding their action. As this remedy is one of the strongest antiseptics known to act upon bacterial life and in particular upon the Loeffler bacillus, it at once appears superfluous to speak of the legion of other drugs which for decades back have been proposed for the treatment of this dreadful disease.

So we can but admit that the methods so far employed in attempting to aid the human organism in resisting this bacterial poison and its products have accomplished but little, if anything at all, *because the remedies we were compelled to use are too weak and because they do not reach the seat of this pathological process.* After coming to this conclusion and throwing aside all superfluous clamor, it behooves us to now attempt to remedy these faults of treatment.

The first imperative necessity brought before us, then, must be to bring whatever remedy we have in direct contact with those bacilli which are in full action upon the tissues. As we can not possibly use the knife and cut down upon the lower stratum of the mucous lining of the tonsils and the pharynx, we must devise other means to bring our drug to the right spot.

For this purpose I have devised an instrument, consisting of three parts: (1) A hypodermic syringe, (2) a tube strong and long enough to reach the pharynx, and (3) a small hollow plate which can be screwed on the end of this tube, holding the points of five hollow needles. When screwed together, these three parts form a firm, handy, and pliable instrument that may easily be introduced over a child's tongue, pressing it down, the points of the needles pointing upward into the pharynx.

Supposing we had a fresh case of diphtheria, and a pseudo-membrane of the size of a pea on the side of the right tonsil. The needles, the tube, and a part of the syringe being filled with an antiseptic fluid, the instrument is passed over the tongue to the tonsils, the returned toward the pseudo-membrane, and, by a quick and gentle pressure, the needles are plunged through the pseudo-membrane and some of the mucosa surrounding it. Now, while three

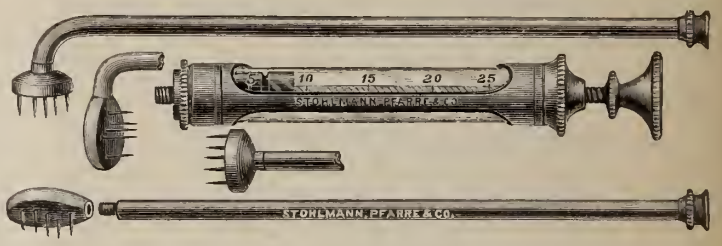

Fig. 4.

fingers of the left hand hold the instrument in this position, the fluid is gently pressed out of the syringe proper and *into and below the inflamed mucosa beneath the pseudo-membrane.* The plate only permits of the needles passing into the tissues to the depth of an eighth of an inch, all told. The needles are then withdrawn, and the remedy is in contact with the seat of the disease.

Five points are used, as I have thought it wise to deposit five distinct little masses of remedial fluid, because the latter would thus cause less inconvenience by pressure, would cover a greater area, and be more readily distributed in the neighborhood. If gently performed, this little operation causes no pain, at least not in adults and children that are sensible enough to speak for themselves. The fluid remains in the tissue, and, as a rule, not a drop of blood is lost.

The curved catheter-shaped tube may be attached to either one of the two plates, so that by the four different combinations any part of the visible pharynx, and even the rear surface of a large tonsil, may be reached.

Intratonsillar injections with a single hypodermic needle have been employed by Heubner in the treatment of scarlatinous amygdalitis for the last eight years, and but lately he has again recommended their use (with a three-per-cent. solution of carbolic acid), yet he does not employ them in primary diphtheria, knowing well that a single injection into the depth of a tonsil would not reach the dis-

Fig. 5.

ease, would be quickly absorbed, and could not be employed in the other parts of the pharynx. But lately, in speaking of diphtheria, he discards all active treatment.

It appears to me of the greatest importance to bring the drug directly *into and below* the diseased part, and to intro-

duce the needles *through and around* the pseudo-membrane. The active bacilli in the *lower* stratum of the mucosa will thus be reached, the tissues there thus made uninhabitable to further possible invasions from above, the exudation must cease, and the whole process come to a standstill. The pseudo membrane, on the other hand, is the *only true guide* to the diphtheric inflammation below it.

After having convinced myself (by practical tests on numerous patients suffering from various throat affections) of the pliability of this diphtheria syringe, I naturally looked about for a remedy for injection. Carbolic acid in a three-per-cent. solution had a good effect on a few cases of tonsillar diphtheria—cases that might possibly have ended as favorably under the use of chlorate of potassium or salt water. To really have a germicidal action, it appeared to me to be essential to use a *very strong* antiseptic—one that would immediately destroy the vitality of the Loeffler bacillus. Here a strong solution of the bichloride of mercury suggested itself, but so far I have been too timid to make use of it. Aniline had lately been mentioned as a non-poisonous antiseptic, and encouraged by Dr. von der Goltz, of this city, who had used the pure aniline in a solution of 1 to 1,000 in a large number of gynæcological and obstetrical cases as an antiseptic wash, apparently with marked success, I concluded to make some experiments to first test its possible poisonous action on the animal system and then its possible antiseptic properties. Assisted by Dr. von der Goltz, I injected four grammes (one drachm) of a ten-per-cent. alcoholic solution of aniline under the skin of a cat, above the gluteal muscles. Thirty minutes after this injection the animal ate a hearty supper, and, after having shown not the slightest sign of poisoning (no change of heart action or respiration in particular), it was killed rapidly by a large dose of chloroform. On section, I found that the aniline had permeated all tissues surrounding the point of injection to the extent of about three inches, and in particular the muscles. A piece of muscle was then put into a large test-tube, and about a teaspoonful of my own saliva added to it. As bacteria are always present in the oral cavity and as I had no cause to think that they were of a particularly virulent type, I argued that, if at all antiseptic, the large quantity of aniline in this muscle would prevent any noticeable bacterial action for some time at least. After forty-eight hours this muscle, soaked full with aniline, was in a high state of decomposition, giving a most offensive smell and showing grayish discoloration on its surface. This simple test was sufficient for me to discard aniline as an antiseptic.

J. Geppert (Bonn), in a series of painstaking experiments, tested some of the stronger antiseptics now in use as to their action upon the anthrax bacillus. I can here but briefly mention his results, showing that this bacillus will live for days in a 7 per-cent. solution of carbolic acid; if hanging in the fibers of a silk thread dipped into a solution of the bichloride of mercury of 1 to 1,000, will live and thrive if removed after twenty minutes; and if spread on a cover-glass and dipped into the same solution, will breed cultures if removed after five minutes. The next tests were made with chlorine water (aqua chlori) of a 0·2-per-cent. solution and of a 0·15-per-cent. solution, which all resulted in showing that the anthrax bacillus was destroyed in ten seconds if brought in contact with this antiseptic, while a 1-to-1,000 solution of the sublimate could not do the same work in fifty seconds. Geppert furthermore showed that that antiseptic was most powerful which was capable of penetrating those media containing the micro-organisms. This also was found to be chlorine. Moist strata are permeated more readily than dry ones. The disinfecting action is a chemical one.

Instigated by these important tests of Geppert's, I resolved to try the action of chlorine water upon the diphtheritic process. Three points had to be considered: (1) if it was safe to inject a 0·2 per-cent. solution of aqua chlori into the tissues without poisonous effect; (2) to determine the local irritation and readiness of absorption if injected; (3) to see if chlorine water would penetrate coagulated blood-albumin and tissue, like epithelial cells and leucocytes.

To determine the safety of hypodermic injections of chlorine water, I injected half a gramme of a 0·2-per-cent. solution of it under the mucous membrane lining the mouth of a white rabbit weighing four pounds and a half. Another rabbit of the same age and weight was kept for comparison. No poisonous symptoms appeared. Even a whole syringeful of this solution, injected hypodermically in the gluteal region, did not impair the animal's health in the least. The injections below the mucosa of the upper lip plainly showed a hard zone for days, evidently due to coagulation of albumin caused by the chlorine after the water had been absorbed. From these experiments I concluded that (1) it was perfectly safe to inject this chlorine water into the mucosa of a child, and (2) that the local irritation caused was not of any account, and that the chlorine evidently immediately went into chemical combinations with the surrounding tissues and was but slowly absorbed. To see if chlorine water would penetrate coagulated blood albumin, Mr. Otto Amend was kind enough to experiment. His answer was an affirmative one. To see if epithelial cells and blood-corpuscles were acted upon, I took a drachm of urine of a patient suffering from pyelitis and purulent catarrh of the bladder, divided the portion in two equal halves in two test-tubes, and added five drops of the chlorine water to the one. After shaking, I took a drop of this mixture and placed it under the microscope. Another drop was taken from the other tube, containing the unmixed urine, upon another slide. Upon comparison, we find that the drop containing urine with chlorine water shows the white blood-corpuscles and epithelial cells acted upon in such a way that their borders look heavy, thickened, and somewhat irregular, the nuclei and nucleoli dark and irregular, and corpuscles as well as epithelium look as though their pictures had been first drawn by pencil and then overdrawn by ink. The constituents of the non-chlorated urine show clear, transparent, and light pictures. (Fig. 5.)

Repeated experiments always gave the same result. Evidently the dark, heavy spots and borders of corpuscles and epithelium were the work of the chlorine and the result of a chemical change caused by the contact of this drug with the albumin of these tissues. I deduced from this

that if chlorine would even penetrate the epithelial cells and the white blood-corpuscles, it certainly would invade every particle of mucous tissue it came in contact with.

I now made chlorine-water injections into the hypertrophied tonsils of adults. Two large drops, divided into five equal proportions by the five needle-points, were injected at one time. The inconvenience caused was hardly noticeable. A sense of pressure appeared, which left the patient after a few minutes. The introduction of the needle-points was hardly felt by the patients.

Being now prepared to use this method and this drug, I made two injections into the tonsillar mucosa of a child of three years, two drops of the 0·2-per-cent. solution being used in each tonsil. This little girl was suffering from a fresh attack of diphtheria of three days' standing, both tonsils showing well-marked pseudo-membranes of doubtless diphtheric character. Glands of neighborhood infiltrated; temperature, 103° F. Sister of child had died of diphtheria a few months before. Injection at 5.30 P. M. Temperature at 9 P. M. down to 101°, and 99° F. next morning. The surrounding parts were now pale, while at time of injection the whole pharynx seemed very red and œdematous. Pseudo-membranes drop off in two days. Appetite of child appeared four hours after injection.

In my second case (a boy, aged two years and three quarters, whose sister had died of malignant diphtheria ten days before) I found diphtheric inflammations on both tonsils, which were in a state of enormous chronic hypertrophy. The right tonsil presented a fresh pseudo-membrane, while the left showed a spot of about a quarter of an inch in diameter, looking as though a drop of milk had fallen on it and spread, the very first sign of a pseudo-membrane. Temperature, 101·75° F.; infiltration of glands; vomiting. Injections, 10 A. M. At 4 P. M. temperature normal; appetite. Pseudo-membrane dropped off within thirty-six hours.

Cases III, IV, and V were very much like this one, all three patients being relatives of Case II.

Case VI.—Boy of four years. Visited a family where a child had been sick with diphtheria three months before. Boy was given toys of this child, especially a trumpet, which had been used by the diphtheric child during its illness. Forty-eight hours after this visit symptoms began. I did not see the child until four days after the visit. Diagnosis: Diphtheria of both tonsils and sides of pharynx, stenosis of larynx, trachea, and larger bronchi, due to diphtheric invasion. Injections of chlorine water through both pseudo-membranous patches in pharynx. Twelve hours later pharynx pale, no extension of pharyngeal diphtheria, the œdema of soft palate subsided; stenosis worse. I now intubated the larynx, bringing but partial relief, as disease had previously extended far below the reach of the O'Dwyer tube. Two days later the child died of paralysis of the heart, but the day before the pseudo-membrane of the pharynx had disappeared entirely. Though in private practice, the parents gave their consent to a post-mortem, which showed an exquisite extension of the diphtheric process all along the bronchi of the first and second order, with formation of pseudo-membrane. The specimen was demonstrated to my class at the New York Polyclinic immediately after the autopsy.

Case VII, the last I shall report, concerned the nine-year-old brother of the little girl in Case II. Illness began suddenly with severe headache and vomiting. Twenty-four hours later I found a dark, slate-colored pseudo-membrane about half an inch in diameter on both tonsils. The whole pharynx œdematous, very red; the uvula much enlarged. Swallowing very difficult. Glands swollen. Temperature, 102·75° F. It needed the assistance of the O'Dwyer-Denhard gag and of three men to overcome the struggling of the boy to succeed in making the first submembranous injection. The second one could be made easily, as the patient lost all fear after the first one, and stated: "If that's all, you can do it again." At the next visit the throat was pale, the swelling reduced markedly, the temperature 100·25° F., the feeling of illness entirely gone, and boy asking for beefsteak. The pallor of the mucosa surrounding the pseudo-membrane was as distinct in this case as in all others. The œdema of the uvula and soft palate had diminished considerably. The next day the general improvement persisted, the left tonsil losing its pseudo-membrane till evening, that of the right growing smaller to one half of its extent. But, as the temperature showed a rise again to 101·5° F., I looked for and found a new diphtheric patch on the side wall of the pharynx back of the right tonsil. I concluded to make another injection at this point, which now was done without the slightest resistance from the boy and without the aid of spoon or gag. Next day both tonsils were clean, temperature was normal, and the pea-like pseudo-membrane disappeared by evening.

These seven cases (from private practice) demonstrate fully—

1. That this method of treatment can be employed without inconvenience and danger to children.

2. That the chlorine water, thus brought in contact with the Loeffler bacilli and the inflamed parts, evidently tends to check their career in the mucous membrane and to shorten the disease.

3. That it seems worth while to give this method a full trial.

One word more about the handling of the apparatus: The chlorine water must be kept cold and dark, and is best carried constantly with the instruments in an outside overcoat pocket. This will insure purity and correct strength of the solution and, before all, will avoid delay, for the sooner the injection is made the better the prognosis of the case. I do not expect to influence cases by this method where the diphtheric inflammation has spread over the half or whole of the oral cavity, and I hardly think that I would make any attempts at using it, but I have good cause to think that we may prevent such spreading by these injections almost with certainty if employed in time.

The needles and the whole instrument are easily disinfected by the same chlorine water and soap and water externally; the inner surface, never coming in contact with diphtheria, is nevertheless disinfected by the chlorine.

The needle-points must be wired carefully and the whole syringe cleared of the chlorine water thoroughly. Of course some corroding will come in time, and a new needle-plate will now and then be necessary; but what is that in comparison to what we may accomplish with it?

Whether the chlorine water will remain the best chemical to use or not, I am not prepared to say. Other remedies may also be used with effect.

In speaking of future methods of treatment in an article published last February I said: "If we now vaccinate organisms into the circulation of healthy persons to prevent disease, why may we not come to impregnating micro-organisms into those already diseased?" And so I hope to see the day when Koch or one of his pupils will give us a lymph that we may inject into diphtheric tissues. By

that time my little instrument may be so improved that it will fully answer this purpose also, yet till then even, I am convinced, it will help to save children from an early grave if employed in time.

PERINEAL CYSTOTOMY *VERSUS* SUPRAPUBIC CYSTOTOMY.*

By H. O. WALKER, M.D.,
DETROIT, MICH.

In the choice of a method of operation we should be governed, first, by its safety; second, by its simplicity of performance; third, by its rapidity of result; fourth, by its general applicability in the majority of cases. It is my purpose in this paper to present briefly my views concerning the two methods of entrance into the urinary bladder—viz., perineal cystotomy and suprapubic cystotomy.

An all-wise Providence evidently intended that the bladder should be emptied from its most dependent point.

Our fathers in surgery, guided by this idea, followed it out by attacking the bladder through the perinæum for the relief of disease, foreign bodies, or obstruction.

One Pierre Franco, in 1556, from force of circumstance, opened the organ from above. Others, at long intervals, did likewise, but all condemned the procedure, largely on account of its high mortality, until Garson and Peterson demonstrated by distention of the rectum the easier approach to the bladder by the sectio alta.

Since the revival of this method the medical press has teemed with fulsome praise of its brilliant results by many advocates, while few have had the temerity to say aught against the tidal wave of opinion in its behalf.

I am aware that I am in the presence of gentlemen distinguished in this department of surgery who do not agree with my views.

It may seem to you presumptuous on my part to offer them from my limited experience, having operated in but five cases, with but one recovery, and by your indulgence I will report them.

Case I.—J. B., aged fifty, first came under my observation in June, 1887, for severe hæmorrhage from the bladder, with a history of the trouble of this viscus of three or four months' standing. His previous history was good, with the exception that, eight years ago, his left arm was severely crushed by a falling trip-hammer, and at that time I removed it just below the shoulder joint. The hæmorrhage was controlled by large doses of ergot. Blood was always present in his urine after this, with evidences of more or less cystitis. The microscope never revealed anything further, but, from exploration of the bladder with a searcher, I have no doubt about the presence of a growth. Medication and irrigation were of no avail in abating his symptoms. On November 25, 1887, as he was gradually failing, he consented that I should operate upon him. At this time reports by various operators were made in the journals extolling the excellence of the suprapubic method, especially for the removal of tumors of the bladder. I therefore concluded that this was a suitable case for its trial. He entered St. Mary's Hospital on November 28, 1887. On December 2d, having undergone thorough antiseptic preparation, I did the operation. As I did not have the rubber colpeurynter, I used a soft-rubber ice-bag, tied on to a No. 16 English catheter, and distended the rectum with ten ounces of warm water, also injecting eight ounces of boric acid solution into the bladder. The incision was about three inches and a half in length, in the median line, to the symphysis, and down to the prevesical fat, which was pushed and torn aside with the finger-nail. The bladder was then seized with two tenacula, and a longitudinal incision made between them. As soon as the boric acid solution had run out there was no difficulty in feeling a tumor projecting on each side and behind the vesical outlet, having its origin from the prostate, although previously I had not been able to recognize any enlargement of the gland by digital examination of the rectum. The tumor was removed piecemeal with the curette, altogether probably of the size of a small egg; it proved to be an epithelioma. The bleeding was profuse, but controlled with hot boric-acid solution. A drainage-tube was introduced and the bladder sutured with catgut, while the abdominal wound was closed with several interrupted sutures of silk. The drainage-tube was of sufficient length to empty into a vessel containing a twenty-per-cent. solution of carbolic acid. On December 3d the patient passed a restless night, with evident dribbling of urine alongside of the tube. On the 4th the condition was the same, with a temperature of 100·5°. On the 5th the temperature was 101·5°; there was constant escape of urine from the wound with suppuration along the course of the sutures. He gradually grew worse, with a varying temperature of 100° to 104·5°, and died on December 28th. The wound never closed, and the whole lower portion of the abdomen, together with the scrotum, was excoriated, as a result of the constant presence of urine. His condition was pitiable, especially for the last two weeks that he lived, although extra effort was made to keep him dry with frequently-renewed dressings. A post-mortem was not permitted.

Case II.—A. L., a Bohemian, aged thirty-seven, first came under my care on May 1, 1888, with a history of previous gonorrhœas, and an operation for a stricture in the deep urethra by external perineal urethrotomy two years before coming to see me. He had a marked chronic cystitis, without evidence of any involvement of the kidneys. It was quite evident from his history that he had had at the time of the urethrotomy a cystitis which had never got well. Although you have observed that my first experience was disastrous, yet, in view of cumulative authority, I again decided to venture the attempt of another suprapubic cystotomy, as this was certainly a proper case for this method. The operation was accordingly done on June 2d, after the manner of the case just described. He did fairly well for ten days, although suffering severely from the presence of the tube, when it was withdrawn, and the wound kept open by the daily introduction of a catheter. From this time on he

* Read before the Mississippi Valley Medical Association at its sixteenth annual meeting.

gradually grew worse, and died on July 10th, evidently by the extension of the disease to the pelves of the kidneys, and possibly the kidneys themselves; yet I was unable to verify this, from the fact that I was out of the city at the time and no autopsy was made

Case III.—M. H., aged seventy, had been a sufferer for over fifteen years from mechanical obstruction of the urine. I saw him for the first time in October, 1888; his prostate was enormously enlarged, and he had all the symptoms common in such cases. I did not see him again until February 6, 1889, in consultation with Dr. Longyear, of Detroit. At this time he was suffering severely from a frequent desire to void his urine. The microscope revealed large quantities of pus, some blood, and epithelial cells, and shreds of tissue that he passed I found to be portions of a sarcomatous growth. I explained to him the possibilities of a suprapubic cystotomy, to which he consented. I did the operation on February 18, 1889. The colpeurynter was distended with about six ounces of water, and that with difficulty. The bladder I found to be of small capacity, holding but a little more than two ounces of the boric-acid solution. In cutting through the bladder it gave the impression as if cutting through cartilage. Introducing my finger, I perceived that most of the bladder was infiltrated with a growth undoubtedly having its origin from the prostate. It was so extensive in character that I did not attempt even to remove any portion of it. A drainage-tube was introduced, through which urine continued to flow until his death, which occurred on March 15, 1889. He died from exhaustion, the natural result of the disease, and not, in my opinion, hastened in the least by the operation.

Case IV.—N. B, aged fifty-nine, a fairly healthy farmer, consulted me, March 14, 1889, for obstruction of urinary flow, necessitating the frequent use of a catheter. Examination revealed a very large prostate, an immense residuum of urine, and a considerable cystitis. He was very desirous that something should be done in the way of an operation, as he had been more or less of a sufferer for five years. Dr. Hunter McGuire's report of excellent results following suprapubic drainage for the relief of enlarged prostates encouraged me to make another trial. The patient entered Harper Hospital on March 21, 1889, and was operated upon on the 23d. For two days he did well, with the exception of constant severe pain and the usual excoriation from the overflowing urine. On the third day he was attacked with peritonitis, although I am certain that no injury was done the peritonæum at the time of the operation. His condition gradually became worse, and he died on the 30th. Unfortunately, the friends objected to an autopsy.

Case V.—A. S., a German, aged seventeen, small for his age, was sent to me by Dr. D. Inglis on January 8, 1890, with a history of painful micturition dating back to the time when he was two years of age. Examination with a searcher revealed a large and hard calculus. Although my previous record was bad, and as this seemed a favorable case, I decided to again try the suprapubic method. He was sent to Harper Hospital, and on January 10th I operated. The usual antiseptic precautions were observed, both preparatory and immediate. He was chloroformed and the rubber colpeurynter introduced into the rectum and filled with six ounces of warm water, and immediately the bladder was distended with an equal quantity of boric-acid solution. This amount of fluid was sufficient to indicate the presence of the bladder above the symphysis. The further steps of the operation were similar to those in the preceding cases, somewhat tedious on account of hæmorrhage, and a mulberry calculus was removed weighing three hundred and twenty grains. The incision in the bladder was carefully closed with interrupted catgut sutures and the integument coaptated with three deep silk sutures, leaving an opening below for a small drainage-tube. The ordinary antiseptic dressings were applied and a rubber catheter was introduced through the urethra into the bladder for draining off the urine.

January 11th.—During the night, owing to pain from the presence of the catheter, the patient pulled it out, and it was quite apparent that the urine was forcing its way through and alongside of the drainage-tube in the wound, showing that I had failed to close the bladder completely. The catheter was again introduced, but its presence was so painful that it had to be removed, and, in spite of all that could be done, the urine continued to flow through the wound.

12th.—For the last twenty-four hours the temperature has ranged from 100° to 102°, indicating that, although we had taken extra precautions for thorough antisepsis, it was evident that our patient was suffering from septic infection. I mention this fact for the reason that several operators speak of the beauties of healthy urine as an antiseptic—to my mind a delusion that should not ensnare any operator, whether his operation is suprapubic or perineal. From this time until January 18th the temperature varied from normal to 102°. The whole of the lower portion of the abdomen and scrotum was excoriated; although extra care was taken to keep him clean, yet the parts were constantly wet with urine.

23d.—The wound was sufficiently closed for the entire urine to pass through the urethra.

29th.—He left the hospital; the wound was completely healed, and he was able to retain his urine for three or four hours.

The perineal method of reaching the bladder is the oldest known to us, although numerous modifications have been made since the hap-hazard "cut on the gripe" for stone was first done. For the removal of stone, litholapaxy undoubtedly stands pre-eminent, and can be done upon subjects from three years of age upward, yet there are numerous restrictions to this method, such as stricture of the urethra, a large-sized stone, an enormous prostate, etc. There can be no question, when cutting has to be done, that the mediobilateral method presents the best advantages, and I can no better illustrate what I wish to say than by quoting the conclusions of Dr. W. T. Briggs, president of the American Medical Association, in his paper, The Choice of Operations for the Removal of Vesical Calculi in the Male: "First, that it opens up the shortest and most direct route to the bladder; second, it divides parts of the least importance; third, it is almost a bloodless operation; fourth, it affords a passage for the removal of any calculus which can safely be removed through the perinæum, and is the best route for free drainage; fifth, it reduces the death-rate to a minimum."

The treatment of enlarged prostates with cystitis is equally efficacious by the perineal section and drainage, in behalf of which I will report the following case—one of many that I have treated in this manner:

O. P., aged seventy four, with a history of prostatic enlargement for twenty years, came under my observation on January 7, 1890, through the kindness of Dr. C. Raynale, of Birmingham, Mich. Until about a year previous he had been able to relieve himself with a catheter, and since that time the desire to void urine had been almost constant, so that he rarely held it more than an hour. I explained to him the possibilities of a perineal section, and after mature deliberation on his part he

consented, and I operated on January 10, 1890. The principles of modern surgery were religiously observed. After dividing the urethra as far as the prostate, I discovered an unusual median projection, which I divided down to the floor of the prostate. The bladder was thoroughly irrigated with a 1-to-10,000 bichloride solution. For a drainage I used a No. 16 common English catheter with about six feet of rubber tubing attached. The catheter was held in place by a silk thread attached to an abdominal hand, care being taken not to permit the point of the catheter to touch the fundus of the bladder; this can be prevented by placing next to the perinæum two or three thicknesses of gauze, and then tying the thread guys close to it on the catheter, over which the other dressings are then applied. It is not necessary to remove the dressings for several days, until all danger of sepsis is past. The tube should be conducted into a vessel containing an antiseptic solution. On the first night following the operation he slept nine hours—something he had not done for years. The bladder was washed out daily with a boric-acid solution through the drainage-tube. For the first ten days he remained in bed; after that he was permitted to sit up and take an occasional walk. During March he had an attack of grippe, to which he nearly succumbed. On July 15th he came to my office informing me that he had just returned from presiding over a two days' session of the Michigan Pioneer Society. He still wears a rubber tube which he keeps closed by a wooden plug, removing it every four or five hours, whenever he wishes to empty his bladder. I was of the opinion, and so informed him, that it was unnecessary to wear it longer, but, as he had had such comfort during its use, he refused to dispense with it.

It is undoubtedly true that by the suprapubic section we are better able to observe a tumor of the bladder, yet it is quite possible with a searcher to recognize its location and size with reasonable accuracy; if more is needed we can resort to the cystoscope. Further, I see no reason why it is not as easily removed through the perinæum as by the high section. In looking up the literature at my command of suprapubic operations since 1883, I find in the record of between three and four hundred operations an average mortality of 30 per cent. A few operators have had a series of cases ranging from three to ten without a death. The most remarkable record in this respect is that of the distinguished surgeon Dr. Hunter McGuire—twenty-one operations with but a single death. When, however, we compare the many thousand operations by the perineal method of different collectors, and find a mortality of but 5, 6, and 7 per cent., rarely going beyond 9 per cent., I must go back to my original propositions and conclude: First, that it is a safer operation; second, that it is a simpler operation; third, that it is more rapid in its results; fourth, that it is adapted to more cases than that of suprapubic cystotomy.

Prescribing Liquors.—"During the recent heated political term in South Carolina a convention met at the county site. The town being a 'dry' one, delegates suffered much from thirst, which fever a thrifty physician sought to allay by prescriptions of whisky and beer. The size of one dose, a dozen bottles, attracted the law's attention, and the medical man is now in the law's clutch. From this he attempts to rescue himself by pleading his professional privilege, but the judge says that while 'prescription' is broad enough to cover a black draught, it lacks elasticity enough for a dozen black bottles."—*Druggist's Circular and Chemical Gazette.*

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. APPLETON & Co.

Edited by FRANK P FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 6, 1890.

THE KOCH TREATMENT OF TUBERCULAR DISEASE.

It is not to be wondered at that the popular and professional interest excited by Professor Koch's announcement of his discovery of a remedy for tubercular disease should be sustained until something decisive occurs, but it is rather remarkable that it should be manifested by certain doings and projects that we have rumors of. Since our last issue, absolutely nothing has been made known that goes far to confirm or to disprove the contention that the remedy is really capable of exerting the curative influence that Koch supposes it to possess, although the announcement has been made that he himself considers his work in the matter at an end and is about to enter upon investigations having for their purpose the preparation of similar antidotes to other infectious diseases.

Physicians from all parts of the world continue to flock to Berlin with the hope of learning something more about the nature and use of the contratubercular "clear, brownish liquid," which the newspapers are practically unanimous in calling "lymph," than is to be made out from what has been published on the subject. As we have said before, it is exceedingly doubtful if they will succeed in their object to any noteworthy extent; nevertheless, we have made arrangements by which anything important about the matter that may be learned by one of them in Berlin will be given to our readers promptly. The worst that is likely to happen to these gentlemen, however, is waste of time; it is far different, unfortunately, with the subjects of tuberculosis who are undertaking a pilgrimage to a distant city. Besides the fact that the efficacy of the Koch treatment is far from being established, there is almost the certainty that the great majority of these sufferers will not have an opportunity to be submitted to it until after their strength has been so exhausted as to seriously impair the probability of their deriving from the treatment whatever benefit it may be capable of conferring under favorable circumstances.

The arrival of specimens of the curative liquid is now expected by several physicians in this country, and it is announced that certain hospitals have set apart wards for patients on whom its virtues are to be tested. If adequate supplies are received, the profession here will soon be able to furnish data on which to found a judgment as to the value of the supposed discovery.

Koch still keeps the secret of the nature of the liquid, and it is intimated that it is his intention to continue to do so for the present. Whatever justification there was for that course at the outset does not seem to be intensified, but rather weakened, by the march of events. The profession will not long rest content with being told that there is too much danger of

their making deadly blunders in case they should try to make the product for themselves. It is stated that the German Government intends to go into the business of making it, and it is announced that that Government has already provided handsomely for carrying the treatment into effect and for Koch's other studies. In the mean time, there are reports of a few deaths having occurred under circumstances that naturally give rise to the suspicion of their having been due to the injections. It still remains to be seen whether Koch's treatment of tubercular disease rests on a wonderful discovery or on a delusion; but, whichever may turn out to be the case, it will undoubtedly lead to processes that will eventually develop our mastery over disease most notably.

SURGERY AND CRUELTY TO ANIMALS.

It is unfortunate that an experiment in bone surgery now in progress in one of the hospitals of New York should have been made the subject of sensational newspaper reports on the one hand, and of condemnation in some of the newspapers on the other. We have reference to the insertion of a segment of a dog's bone into a vacuity in the bone of a boy's leg, the segment being still connected with its original source of blood-supply, so that the dog requires to be kept almost motionless for a long period, and otherwise treated by restraining measures. All this, of course, would be inexcusably cruel if it were done wantonly or with no sufficient laudable purpose in view, and a portion of the public is apt to lose sight of the praiseworthy object, and dwell on the dog's sufferings. This tendency is necessarily heightened when a writer of ability argues in one of the daily papers that the experiment is unnecessary and therefore unjustifiable, and when his argument receives editorial support. This is what has happened, and the danger is that a public feeling will be aroused that will lead the Legislature to cripple experimentation by the enactment of more stringent laws against cruelty to animals. Legislation engendered by sentiment is prone to go too far, and, to avoid such a result in this matter, it ought to be made known to the good people who are distressed at the boy-and-dog experiment that it certainly was not undertaken as a mere exhibition of caprice, assuredly not as a piece of cruelty. There may be equally good methods of filling a bony gap with new bone; there may even be better ones. That, however, has not yet been made a matter of certainty, although the success obtained by Mr. A. G. Miller, of England, with the use of decalcified-bone chips, alluded to in our last issue, has been such as to afford great encouragement that it soon may be demonstrated. Until it has been, a surgeon is justified, we think, in using his own judgment in the choice between a procedure involving suffering to one of the lower animals and one that does not involve that occurrence. This is not a matter of vivisection in the ordinary sense of the word, and it will not do to cite the statements of physiologists against the utility of the operation. On the other hand, members of the medical profession can not be too careful, when they set about any such procedure, to take all possible pains to carry it out with every practicable mitigation of suffering. We have no reason to think that this was not done in the instance that has been made the subject of comment.

MINOR PARAGRAPHS.

THE USE OF MENTHOL IN DIPHTHERIA.

The antiseptic properties of menthol, especially in cases of diphtheria, have received strong testimony in an article by Dr. Herman Wolf in the *Therapeutische Monatshefte* for September. He adopts the following form of application: A powder is prescribed containing one part of the drug to ten or twenty parts of sugar; this to be carefully applied by means of a camel's-hair brush to the inflamed and membrane-covered parts of the throat, which should have been thoroughly cleansed from all mucous secretions beforehand. If the nasal passages also are involved, the powder should be blown into the anterior nares and upon the posterior pharyngeal wall. If the process has invaded the bronchi, menthol may be sprayed during inhalation. In a somewhat large experience with it, Wolf declares that he has found the drug free from all toxic tendencies, while at the same time it is a complete and prompt local antiseptic in this class of cases. As he uses it, the drug is unobjectionable in odor and taste, and has more potency than many of the gargles and sprays that are in common use, but which are far more disagreeable. In the light of the latest investigations the rôle of antiseptic applications is strengthened in the treatment of this disease. The recent experimental work of Wintgens and others show, in regard to the Klebs-Löffler bacillus, that it is capable of producing an exceedingly poisonous albuminoid when cultivated in suitable nutrient media. These researches confirm the clinical value of those antiseptic applications that destroy the virulent bacillus, of which menthol is reported to be one.

DECENTERED SPECTACLE GLASSES.

It is the exception rather than the rule to see persons, in the medical profession as well as out of it, wearing spectacles and eye-glasses the centers of the lenses of which correspond with the visual axes. That more or less asthenopia may be produced by a faulty position of the lenses has been admitted by ophthalmologists, and in these days when attention has been directed so strongly to the ocular muscles it may not be amiss to ask whether certain cases of muscular weakness are not due to an habitual faulty position of a lens employed to correct a refractive error. A lens may be regarded as formed of an infinite number of minute prisms, each with a different refracting angle, and the only ray not refracted by a lens is the one which passes through the center of each surface. If the lens is so placed that these centers, instead of coinciding with the axis of vision, are displaced in any direction, a prismatic effect is obtained, the line of vision is bent toward the center of the lens if it is convex, from the center if it is concave, and the cornea is drawn in the opposite direction to counteract this effect and restore the line of vision to its normal position. The muscle or muscles which act to produce this position of the cornea and correct the interference in the line of vision are habitually overworked. When the displacement is not great in amount, the additional work thrown upon this muscle is not noticed by the wearer of the lens, but it seems as if it must result in a certain amount of muscle strain proportionate to the strength of the lens and the degree of displacement of the center, which may be followed by asthenopic symptoms. These considerations should induce a greater degree of attention to the accurate adjustment of the centers of the lenses to the visual axes—atten-

tion which can be paid by the general practitioner as well as by the ophthalmologist, but is usually relegated to the local optician or jeweler, whose sole idea is to sell his customer a pair of glasses with which he can see well, and who knows nothing about these evil after-effects of decentered lenses.

IRREGULARITIES IN THE CUTANEOUS MANIFESTATIONS OF TYPHOID FEVER.

Dr. R. L. MacDonnell, in a clinical lecture, in the *Montreal Medical Journal* for November, has pointed out some atypical conditions of the skin among his cases at the General Hospital. The number of patients with the disease—seven men and five women—was somewhat larger than usual at this season of the year, but the type of the disease has, for the most part, been a mild one. Unilateral sweating was noticed in the case of a strong young Englishman who had a fairly severe attack of the fever; on the day of his admission the one-sided sweating was well marked, but it had disappeared three days later. In one case a pale scarlatiniform rash was noted within a few hours after admission, confined to the neck and shoulders; it was of short duration. No medicines had been administered. In the case of a young girl, urticaria in distinct wheals manifested itself in the third week of an attack that had not been severe. In the case of a pregnant woman, who had a protracted attack of typhoid, there was jaundice lasting three days. In the case of a man who had a sharp attack, with extreme meteorism, for the relief of which turpentine stupes were used, pustules appeared upon the abdomen at the site of the typhoidal eruptive spots; in some of these small abscesses, containing from half a drachm to a drachm of pus, were formed. This accident Dr. MacDonnell had noticed once before as a result of the use of turpentine stupes in fever. Four irregular forms of eruption in typhoid fever have been specified by Moore, of Dublin, such as erythema fugax, miliary eruptions, erythema simplex (seu scarlatinale), and urticaria. The scarlatiniform rash is most likely to show itself at the end of the first week or in the course of the third week, and when it appears early it is apt to give rise to diagnostic embarrassment, but the prodromes of scarlet fever are wanting, and the rash has been of a lighter color, less rough and punctiform than that of the exanthem: the rash is a blush rather than an eruption, and may be considered as a result of some disturbance of the peripheral vaso-motor system.

LEPROSY IN COLOMBIA.

An official report on the rapid spread of this disease is contained in a recent number of the *Revista de Higiene de Bogotá*. It is the result of systematic medical inquiries throughout the republic regarding the causes and phenomena of the disease by the Central Junta of Hygiene of Colombia. The propositions of this medical commission are of interest in respect of the primary steps of relief that will be recommended to the executive and legislative departments of the Government: 1. To solicit the next Congress to pass a law providing for the isolation of individuals affected with leprosy and elephantiasis. 2. To establish a special tax to defray the expense of observing the method of propagation of the disease and for the erection and maintenance of lazarettos; and to include this tax in the central budget of the Government.

THE VIENNA SYSTEM OF PUBLIC BATHS.

Mayor Grant has had laid before him a proposal for the erection of free baths on a plan like those now in successful operation in Vienna. The object of this plan is to supply public baths which can be kept clean and free from contagion. In order to accomplish this, shower-baths only will be used, the water being allowed to flow off into the sewer as fast as it is used. The buildings for this sort of baths need not be situated on the river front, but may be in the very heart of the city. It is calculated that a building on an ordinary city lot may be so arranged as to accommodate a thousand bathers daily. Each bath will be in a separate compartment, with towel and soap for each. The baths may be divided into two classes—those absolutely free, and those for which a charge of five cents is made for some little additional attendance. The city authorities will be asked to furnish the water free of cost in one or more experimental bath-houses that will soon be established in the populous eastern regions of the city.

GREEN COFFEE IN MIGRAINE AND GOUT.

Green coffee, in the form of an infusion or fluid extract, was formerly somewhat used in migraine, but has fallen into disuse, partly, as we believe, from its taste being essentially disagreeable to many patients. Recently Dr. Lauderbilco has bespoken, in the *Journal de médecine de Paris*, its retrial. He recommends the use of the infusion in the treatment of gout, gravel, nephritic colic, and migraine; the varieties of coffee to be used are Martinique one half, and Mocha and Isle de Bourbon berries, each, one quarter. Six drachms of this mixture are placed in a glass of water and macerated for twelve hours; the contents are then strained and the clear liquid is drank, without the addition of sugar and while the stomach is empty, preferably before breakfast. Food may be taken soon afterward. The results are described as having been so satisfactory that the author gives the green coffee a strong recommendation in cases of a gouty tendency.

DR. SOLIS-COHEN'S LECTURES.

In this issue we conclude the publication of Dr. Solomon Solis-Cohen's two lectures on the Therapeutic Principles governing the Selection of Cardiac Medicaments. They were delivered in the course at the Medical Department of Dartmouth College. We must congratulate that institution and the Philadelphia Polyclinic on having a lecturer capable of elucidating such a subject so clearly as Dr. Solis-Cohen unquestionably has done. It is one that practitioners in general are by no means versed in, and can not readily acquire exact information upon, except by a wide range of reading or by some such condensed but thorough exposition as is given in these lectures.

THE ATTRACTIVENESS OF CHICAGO TO PHYSICIANS.

It was stated at the recent annual meeting of the Illinois State Board of Health that at no time since the organization of the board had there been such an influx of physicians into Chicago as within the preceding three months, during which time more than two thirds of the licenses issued to practice medicine were to practice in Chicago. It was also stated that never before had there been such a number of quacks trying to get a foothold in that city. This was partly attributed to the attractiveness of the prospective fair, and partly to the increase of population.

A FORECAST IN REGARD TO CHOLERA.

Dr. J. H. Rauch is reported as having said, at the recent annual meeting of the Illinois State Board of Health, that a conference with the health officials of Great Britain and Germany had given him the impression that they agreed in thinking that there was great danger of the spread of cholera next

year; and as having added that, after a careful review of the situation, he felt that this country also was in great danger of its introduction, though by extreme vigilance at the maritime ports this might be prevented.

THE ILLNESS OF THE SURGEON-GENERAL.

As we go to press, the news in regard to General Baxter's condition is, we regret to say, not encouraging. He is reported as still in a state of coma, which has been continuous since the apoplectic seizure that occurred on Monday. We still hope for information of a favorable change in his case, for he was in the height of his mental vigor when he was stricken down, and gave promise of much valuable service in the medical corps of the army.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 2, 1890:

DISEASES.	Week ending Nov. 25.		Week ending Dec. 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus fever	0	0	1	0
Typhoid fever	23	7	25	3
Scarlet fever	70	8	93	9
Cerebro-spinal meningitis	2	2	3	3
Measles	193	11	225	12
Diphtheria	78	26	90	28
Small-pox	1	0	1	0
Varicella	5	0	12	0

The Muetter Lectures of the College of Physicians of Philadelphia.—The course of lectures on surgical pathology provided in accordance with the will of the late Professor Thomas D. Mütter will be delivered during 1890–'91, by Professor Roswell Park, of Buffalo, N. Y. The first series of five lectures will be given in the hall of the College of Physicians, corner of Thirteenth and Locust Streets, on December 4th, 5th, 6th, 8th, and 9th, at 8.15 P. M. The subjects are as follows: 1. Introductory. Study of the blood and of some phases of the inflammatory process. Thrombosis, embolism, hæmoglobin and oligochromæmia, ptomaines. Conditions predisposing to infection. 2. A study of pus and of pyogenic organisms, obligate and facultative. 3. Surgical sepsis and the organisms which produce it. Résumé of experimental work, surgical fever, intestinal toxæmia, sapræmia, septicæmia, and pyæmia. 4. Peritonitis—forms and causes. Testing the relative values of antiseptics. 5. Tetany and tetanus. The medical profession are cordially invited to be present.

The Mattison Prize.—With the object of advancing scientific study and settling a now mooted question, Dr. J. B. Mattison, of Brooklyn, offers a prize of $400 for the best paper on Opium Addiction as related to Renal Disease, based upon these queries: Will the habitual use of opium, in any form, produce organic renal disease? If so, what lesion is most likely to occur? What is the rationale? The contest is to be open for two years from December 1, 1890, to either sex and any school or language. The prize paper is to belong to the American Association for the Cure of Inebriety, and be published in a New York medical journal, in the *Brooklyn Medical Journal*, and in the *Journal of Inebriety*. Other papers presented are to be published in some leading medical journal, as their authors may select. All papers are to be in possession of the chairman of the award committee on or before January 1, 1893. The committee of award will consist of Dr. Alfred L. Loomis, of New York, chairman; Dr. H. F. Formad, of Philadelphia; Dr. Ezra H. Wilson, of Brooklyn; Dr. George F. Shrady, of New York; and Dr. J. H. Raymond, of Brooklyn.

The Gastric Juice in Diabetes.—"In a long article on the condition of the gastric juice, saliva, and perspiration in diabetes, Dr. Ponomaroff details a number of observations which lead him to dispute the assertions of some previous observers—*e. g.*, Heller and Frick, who believed that they had detected sugar in these secretions. With regard to the gastric juice, Dr. Ponomaroff points out that where this is obtained by making the patients vomit, what is obtained is not the gastric juice alone, but an admixture of that with a certain quantity of bile. This generally contains sugar, and therefore vitiates the result. When the œsophageal tube is used and the gastric juice free from bile is obtained, there is, he states, never any sugar in it."—*Lancet.*

The New York Academy of Medicine.—At the next meeting of the Section in Surgery, on Monday evening, the 8th inst., Dr. W. T. Bull will report Three Cases of Pylorectomy for Cancer of the Stomach, and Dr. R. F. Weir, A Case of Gastro-enterostomy by Abbe's Rings for Pyloric Stenosis, with Remarks.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 9th inst., Dr. F. R. Sturgis will read a paper on a subject to be announced, and Dr. Robert W. Taylor one entitled Certain Clinical Features of Chancre of the Fingers.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 11th inst., the chairman, Dr. L. Emmet Holt, will show a patient who has recovered after symptoms indicating a tumor of the brain; Dr. W. E. Forrest will read a paper entitled Observations upon the Influence of Artificial Respiration on the Heart of the Newly Born; Dr. G. W. Rachel, one on Polyuria in Infancy; and Dr. B. Scharlau, one on The Treatment of Large Serous Effusions into the Chest by Incision.

The Brooklyn Surgical Society.—The special order for the meeting of Thursday evening, the 4th inst., was the report of a case of œsophagotomy, by Dr. Jarvis S. Wight.

The Medical Society of Pennsylvania, according to the Philadelphia *American*, has recently applied for a charter.

An Organization of Railway Surgeons.—The surgeons of the Pittsburgh and Lake Erie Railroad have organized, with Dr. J. P. McCord, of Pittsburgh, as president, for the purpose of improving their co-operation in their work.

The Journal of the American Medical Association.—It is stated that a resolution will be submitted to the next meeting of the association, making Washington, D. C., the permanent place of publication of the *Journal.*

The Medical Societies of Louisville are reported to have joined in the undertaking of procuring a building for their meetings and for a library and museum.

The Buffalo Medical College.—It is announced that the college building is to be remodeled and added to so that its area will be 207 feet on Virginia Street and 55 feet on Pearl Place.

The Worcester, Mass., Lunatic Hospital.—Dr. Hosea M. Quinby has been appointed superintendent.

The Maine Insane Hospital.—Dr. P. H. S. Vaughan, of Skowhegan, has been appointed an assistant physician.

Change of Address.—Dr. Leo Ettinger, to No. 101 East Sixty-first Street.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 23 to November 29, 1890:*

Ewing, Charles B., Captain and Assistant Surgeon, in addition to his present duties, is assigned, by direction of the Secretary of War, to duty as examiner of recruits at St. Louis, Mo. Par. 7, S. O. 275, Headquarters of the Army, A. G. O., November 24, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 29, 1890:*

Crawford, M. H., Passed Assistant Surgeon. Ordered to the Receiving-ship Independence.

Marsteller, E. H., Passed Assistant Surgeon. Ordered to the U. S. Steamer Petrel.

Nash, Francis S., Passed Assistant Surgeon. Resigned from the U. S. Navy, to take effect November 23, 1891.

CORDEIRO, F. J. B., Passed Assistant Surgeon. Granted extension of leave for four months, with permission to leave the United States.

LANSDALE, PHILIP, Medical Director (Retired). Granted one year's leave, with permission to leave the United States.

ALFRED, ADRIAN RICHARD. Commissioned an Assistant Surgeon in the U. S. Navy, from November 24, 1890.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the week ending November 22, 1890:*

FESSENDEN, C. S. D., Surgeon. Granted leave of absence for fourteen days. November 22, 1890.

AUSTIN, H. W., Surgeon. Detailed as chairman of Board of Medical Officers to convene in Washington, D. C., December 1, 1890. November 19, 1890.

IRWIN, FAIRFAX, Surgeon. Detailed as member of Board of Medical Officers to convene in Washington, D. C., December 1, 1890. November 19, 1890.

KINYOUN, J. J., Assistant Surgeon. Detailed as recorder of Board of Medical Officers to convene in Washington, D. C., December 1, 1890. November 19, 1890.

WOODWARD, R. M., Assistant Surgeon. Granted leave of absence for fourteen days. November 21, 1890.

CONNICT, A. W., Assistant Surgeon. To proceed to Cairo, Ill., for temporary duty. November 19, 1890.

STIMPSON, W. G., Assistant Surgeon. To proceed to Cape Charles Quarantine for temporary duty. November 20, 1890.

Promotion.

KINYOUN, J. J., Passed Assistant Surgeon. Commissioned as Passed Assistant Surgeon by the President. November 21, 1890.

Appointment

COFER, L. E., Assistant Surgeon. Commissioned as Assistant Surgeon by the President. November 21, 1890.

Society Meetings for the Coming Week:

MONDAY, *December 8th:* New York Academy of Medicine (Section in Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private); Lenox Medical and Surgical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, *December 9th:* New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Medical Societies of the Counties of Chemung (quarterly—Elmira), Oswego (semi-annual—Oswego), Rensselaer, and Ulster (quarterly), N. Y.; Norfolk, Mass., District Medical Society (Hyde Park); Newark, N. J., and Trenton (private), N. J., Medical Associations; Morris, N. J., County Medical Society (semi-annual); Baltimore Gynæcological and Obstetrical Society.

WEDNESDAY, *December 10th:* New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Societies of the Counties of Albany, Cayuga (semi-annual), Cortland (semi-annual), and Montgomery (quarterly), N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

THURSDAY, *December 11th:* New York Academy of Medicine (Section in Pædriatics); Society of Medical Jurisprudence and State Medicine; New York Physicians' Mutual Aid Association (annual); New York Laryngological Society (annual); Brooklyn Pathological Society; Medical Society of the County of Cayuga; South Boston, Mass., Medical Club (private—annual); Pathological Society of Philadelphia.

FRIDAY, *December 12th:* Yorkville Medical Association (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties.

SATURDAY, *December 13th:* Obstetrical Society of Boston (private).

Letters to the Editor.

ALVEOLAR ABSCESS; A REPLY TO DR. J. D. MacPHERSON.

104 EAST FIFTY-EIGHTH STREET, NEW YORK,
November 24, 1890.

To the Editor of the New York Medical Journal:

SIR: Since the establishment of a section in dental and oral surgery in the last two International Medical Congresses, and the incorporation of a similar section in the American Medical Association, the recognition of dentistry as a distinct specialty of medicine, when practiced by medical men, has been generally recognized.

In behalf of the large number of medical men who devote their entire energies to the treatment of dental and oral difficulties, I would enter a protest against the correctness of the deduction made in an article published in your valuable journal for November 22, 1890, by Dr. J. D. MacPherson, on The Importance of Prompt Treatment in Alveolar Abscess.

We as dentists have to keep well informed in general medicine, yet constantly in practice are we embarrassed by the lack of correct information of the profession at large on simple dental topics. Nothing illustrates this more readily than the errors the above-mentioned author falls into as soon as he verges upon a strictly dental sphere.

His classification of alveolar abscess into superficial and deep is rather original, but will scarcely be adopted by an investigator. His term superficial evidently refers to an old chronic abscess having an old fistula leading to the source of trouble, while by deep is meant an acute attack of alveolar abscess. His criticism on dentists failing to extract teeth when the tissues are in a state of inflammation must be due to a misconception of facts by the author. Never have I known or heard of a dentist delaying extraction when once it had been determined upon for such a cause. Except for dispensary patients, it is rare indeed that a tooth must be extracted on account of an alveolar abscess. The main object of this communication is to combat the conclusion made that immediate extraction of the tooth is demanded. Dentistry may keep on improving, but artificial teeth will be as good as living ones about the time that artificial noses, eyes, limbs, etc., are as good as living ones. The general medical practitioner places altogether too small a value on the utility of each individual tooth and its function as a part of the general digestive apparatus.

With some rare exceptions, common alveolar abscess is caused by the putrefaction of a dead pulp, the gases of which, escaping through the apex of the tooth, produce an inflammation of the pericementum (not periosteum) resulting in suppuration, etc. Let us remember that in these cases the tooth itself is not necessarily dead. In the vast majority of cases where treatment is properly instituted, the tooth never dies, but circulation is carried on through the living membrane in the alveolar socket, the pericementum. The course pursued by the dental surgeon in these cases is to first adjust a piece of rubber dam so that no saliva can come in contact with the tooth and infect the pulp canal. An opening, if not already found, is drilled through the crown of the tooth into the pulp chamber on a line leading direct to the apices of the roots. The opening is made sufficiently large and deep for every vestige of pulp tissue remaining in any of the roots to be entirely removed. This at once relieves the sufferings of the patient. The canals are then thoroughly syringed with a solution of chemically pure peroxide of hydrogen and bichloride of mercury; after this, by means of a cauterizing wire, the canals are completely dried. Their sides are then wiped with one of the essential

oils, and the apex of the root is hermetically sealed with some material like a solution of gutta-percha in chloroform, and the tooth is filled in the customary manner. If any inflammatory action sets in after such an operation is properly performed, the seat of the trouble is no longer in the tooth, but in the apical space, and it is generally effectively treated by abortive measures; if it is more serious, an opening is made through the alveolar process and simple surgical measures are used. The great danger in all these cases arises from the septic symptoms liable to occur, due to the absorption of pus. The most dangerous and insidious cases are those in which there have been established fistulæ leading outside the alveolus. The pain subsides, and, the patient paying no further attention to the matter, the abscess lapses into a state of chronicity, classified as superficial by Dr. MacPherson, because when, after short intervals of rest, the foul pulp in the tooth starts up the latent abscess, it requires very little pressure for it to force its way through its old channels and out of the alveolus, leaving behind a zone of necrotic tissue, affecting also the apex of the tooth. Only in such cases as these can any part of the tooth be said to be dead. Even here, if the tooth is treated as before mentioned, and the alveolar tract enlarged down to the root, removing all the dead portion of the tooth, as well as the necrotic tissue surrounding it, the parts will all return to a condition of health and the tooth continue to do good service even after half of the root is amputated.

M. L. Rhein, M. D., D. D. S.

THE GONOCOCCUS OF NEISSER AND ARTHRITIC EFFUSIONS.

667 Madison Avenue, *November 13, 1890.*

To the Editor of the New York Medical Journal:

Sir: In an article by Dr. H. Koplik, entitled Arthritis complicating Vulvo-vaginal Inflammation in Children, published in the Journal for June 21, 1890, I note the following: "Petrone and Kammerer relate cases in which they have discovered the diplococcus in joint effusions in both the male and female. Kammerer questions the investigations of Brieger and Ehrlich as to the presence of the micro-organism of Neisser in joint effusions, and states that the joint fluid should be examined very soon after infection of the urethra—three to five days. If this be done they can be easily demonstrated. It is an ungrateful task to criticise the work of others, but, in a true spirit of investigation, I beg to say that I have carefully looked into the work of Kammerer in the two cases above mentioned, and find only the statement of the presence of diplococci; these were found simply free, not in the pus cells, and there were no cultures made."

I should feel loath to question the investigations of two such workers in the field of pathology as Brieger and Ehrlich. I only tried to give an explanation of the unsuccessful attempt of these two gentlemen to find micro-organisms in the effusions of gonorrhœal rheumatism, and suggested that their cases might have been of older standing, in which the cocci had disappeared in the fluid. But I have nowhere stated, as is attributed to me, that gonococci can be easily demonstrated in effusions from three to five days after infection of the urethra. If the author of the paper had "carefully looked into" my work, I do not think he could have attributed this statement to me. I have never asserted that gonococci could be "easily" demonstrated in the joints; on the contrary, I distinctly said that in the only case in which I had found them they were present in small numbers. I stated at the time of my publication that the three cases that had yielded a positive result on microscopic examination of the joint effusion had been examined within five days after the appearance of the joint affections, but I drew no general conclusions. That I am, however, also credited with having said the joint fluids should be examined three to five days *after infection of the urethra*, is an oversight on the part of the author difficult to explain. I, at least, have never seen a joint affection developing in so short a time after infection of the urethra, and have consequently made no assertion to this effect.

That I relied only on the grouping, staining, and size of the cocci in classifying them as the coccus of Neisser, and made no cultures, is a matter I regret as much as Dr. Koplik. During the summer of 1883, when these cases came under my observation, the knowledge of the methods of bacteriological culture was the privilege of only a favored few. Since then, however, I have become acquainted with the difficulties attending the cultivation of the coccus Neisser on blood serum, and on that account, I believe, its cultivation from the effusions in joints will seldom prove a success.

Whether the coccus Neisser or some pyogenic germ is the cause of the joint affections in gonorrhœal rheumatism is, I presume, still an unsettled question. Many observations in both directions have been published. Judging from the different character of the effusion and the different clinical course which these affections pursue, I think that both modes of infection are possible—a view which I am not the first to express. However this may be, I have always believed that the main value of my paper, if indeed it had any, lay in the discovery of micro-organisms in the joints, not especially of the coccus Neisser.

Frederick Kammerer, M. D.

THE LIBRARY OF THE NEW YORK HOSPITAL; AN ERROR CORRECTED.

New York, *November 29, 1890.*

To the Editor of the New York Medical Journal:

Sir: At the recent inauguration of the new Academy building an address was delivered by one of the speakers, upon the subject of Our Library, which contained the following very *erroneous* statement: "Thirty-three years ago, when I was admitted a member of this Academy, there was no medical library or medical reading-room in this city."

Whence the writer got his information I know not, for so frequently has the history of the library of the New York Hospital been written and published by city compilers and by United States Government officials that it seems strange that one possessed of the general information of the speaker should not have known that the library of the New York Hospital was founded in 1796, and that when he became a member of the Academy it contained 6,180 volumes and occupied three apartments, two of them on the second and third floors of the old hospital, joined by an iron staircase. All this was as far back as 1857; thus it appears that our city *had* a medical library of no mean capacity thirty-three years ago, and was used by the profession and by students of medicine.

John L. Vandervoort, M. D., *Librarian.*

THE LARYNGOLOGY OF TROUSSEAU AND GREEN.

Home for Incurables, Fordham, N. Y., *October 30, 1890.*

To the Editor of the New York Medical Journal:

Sir: In your issue for August 30th, current year, there is an article on the Laryngology of Trousseau and Dr. Horace Green, by Dr. Frank Donaldson, of Baltimore, to which I wish to add a few historical corrections, so as to make that article complete. In 1838 Dr. Green went to Europe, accompanying the Rev. Dr. Schroeder, of Astoria. It was at that time that Dr. Green had the conversation with Dr. James Johnson, the editor of the *Medico-chirurgical Review*. Subsequently to that, the *British and Foreign Medical Review* was established, with Dr. John Forbes as editor. After Dr. Green's return from Europe he

commenced to make a practical application of the treatment which had been suggested to him by Dr. Johnson in his conversation, and in 1846 he published his treatise on *Bronchitis*, in which the results of his work in that direction were given to the public. In 1849 I went to Europe and carried with me a number of copies of Dr. Green's work, which had been handsomely noticed by Dr. Forbes in the *British and Foreign Medical Review*. I remained in Europe until the fall of 1852. While in Paris, I recollect that the author of the article, Dr. Frank Donaldson, of Baltimore, was a fellow-student at the same time, attending Professor Trousseau's lectures at the Children's Hospital. Until then Dr. Green's treatment had been by means of the sponge probang. During the summer of 1852 I wrote to Dr. Green that it was time for him to come abroad and look after his own interests. He accordingly came, and had an interview with Professor Trousseau at the Hôtel Meurice in Paris. I returned to this country with him in October of that year. In 1854 I made a second visit to Europe, and while in Paris I had an interview with Professor Trousseau, who was then at the Hôtel Dien, having taken to him a letter of introduction from Dr. Barker, who was Dr. Green's colleague in the New York Medical College. I attempted to demonstrate upon a patient in the wards under Professor Trousseau the feasibility and practicability of carrying a sponge-armed probang into the larynx and below the vocal cords into the trachea, so as to convince Professor Trousseau. He still persisted in denying its feasibility, and I accepted his invitation to demonstrate it upon a body in the dead-house of the hospital. We all went down into the dead-house. I passed the instrument, and then performed on the body the operation of tracheotomy, and saw the probang in the larynx through the opening made in the trachea. Professor Trousseau then objected because the vital conditions were changed by the death of the subject. I then undertook to make some experiments on the dead body at Clamart, well known to students of anatomy in Paris. I carried a catheter which was made more or less firm by the introduction of a mandrin which I had made purposely, articulated to the end of which I secured a sponge of about the size of that used by Dr. Green on the probangs in his office. My experiments were successful, and I then received the impression that a tube of the caliber of the catheter might be used with success to inject through it a weak solution of nitrate of silver. The result of this experimentation I wrote to Dr. Green, and while I was on shipboard. On my return home, Dr. Green had instituted a practice of catheterism of the air-passages by which a weak solution of nitrate of silver could be carried into the trachea, and, as he averred, lower down into the right or left bronchus, at will. Until then the term catheterization had not been used.

J. H. Douglas, M. D.

HYDROGEN PEROXIDE IN DIPHTHERIA.

1189 Madison Avenue, *November 8, 1890.*

To the Editor of the New York Medical Journal:

Sir: I would suggest the following local treatment for diphtheria: The application to the membrane of Marchand's solution of peroxide of hydrogen, fifteen volumes, with an equal bulk of water, then scraping the membrane off with a curette and applying the peroxide of hydrogen, one third dilution, every hour for six or seven hours, then every two hours. If there is no reappearance of membrane after two days, spray the throat occasionally with an antiseptic spray. In this way the membrane is removed at once. The operation is done at a period of the disease when there is no danger of heart failure, so that the struggles of a child need not be minded.

I am aware that the removal of the membrane in former years was regarded as somewhat dangerous, but at that time nothing was known of disinfectants and germicides.

It would seem that a remedy which, applied to the diphtheritic membrane, removed it after some hours, would prevent its formation. In tolerant patients the peroxide may be put on three or four times, so as to be sure of complete disinfection before curetting. A small Thomas's uterine curette answers the purpose admirably. A patient treated as described was comparatively well in two days.

David Phillips, M. D.

LIGATION OF THE LIMBS IN HÆMORRHAGE.

Adirondack Cottage Sanitarium, *November 11, 1890.*

To the Editor of the New York Medical Journal:

Sir: A certain contributor to the Journal of November 1st, page 488, would have us believe that he was the original discoverer of the process of ligating the limbs for hæmorrhage! He "*would suggest* the following plan," and, having "made extensive use of these bands," can "now feel a good deal of confidence in recommending them to others," etc. Does he not know that this procedure is as old as the hills, and is called *ligation of the base of the extremities* in every standard text-book on minor surgery, not to mention the many encyclopædic articles on hæmorrhage and hæmostasis? It would not be just to the history of our art to allow such a presumption to pass unnoticed.

W. W. Skinner, M. D.

Book Notices.

Klinische und anatomische Beiträge zur Pathologie des Gehirns Von Dr. Salomon Eberhard Henschen, Professor der klinischen Medicin, Direktor der medicinischen Klinik an der Universität Upsala. Erster Theil. Mit 36 Tafeln und 3 Karten. Upsala: Almquist & Wiksell, 1890. 4to, pp. 215.

These magnificent clinical and anatomical contributions to the pathology of the brain emanate from the University of Upsala, Sweden. The book, however, is not written in Swedish, but in German, which, fortunately, will make it practically useful to all nations. It is well known that much of our present knowledge of the physiology and pathology of the human brain is the result of careful study of rather poorly reported cases scattered through the literature of past years, and collected at a time when the thoroughness and completeness of clinical observation were not so great as now. Every investigator who endeavors to make use of this old material for the solution of new problems soon ascertains how defective and often even useless it is. A new and richer material is desirable to insure the progress of cerebral pathology. With this object in view Professor Henschen has issued this first volume of his work, a second being also nearly ready. The author believes it necessary, in such clinico-pathological studies, to accompany them with systematic drawings or photographs of the pathological lesions in their natural size. Hence the issue of this book in quarto form to give space for the thirty-six plates which illustrate the text. It may be remarked here that these plates are marvels of lithographic art. A number of them are in color, reproducing perfectly sections stained by the Weigert method.

This whole volume deals with the clinical manifestations and pathological findings in lesions of the optic tract, and is based upon thirty-six cases which have come under the author's observation, in nearly all of which autopsies have been made. The histories of these cases, together with the description of the autopsies and microscopical examinations—all of which are

written with remarkable scientific precision and detail—are grouped into fourteen chapters with the following headings:

1. Secondary changes in the optic tract in a case of bilateral bulbar atrophy (one case).
2. The visual path in one-eyed persons (eight cases).
3. Changes in the optic tract in lesion of the corpus geniculatum externum (two cases).
4. Hemianopsia following gummatous basal meningitis (one case).
5. Tumors of the chiasm (two cases).
6. Hemianopsia from hæmorrhage into the thalamus (one case).
7. Visual disturbances from bilateral changes in the optic radiations (three cases).
8. Hemianopsia following softening of the optic radiation (two cases).
9. Cortical hæmianopsia (three cases).
10. Tumors in the optic radiation without hemianopsia (three cases).
11. Cortical changes in the occipital lobe without hemianopsia (two cases).
12. The visual path after lesion of the optic radiation (one case).
13. A contribution to color hemianopsia (two cases).
14. Cases of hemianopsia (five cases).

It would be impossible in a short review to call attention to all the invaluable features of this book. It is hoped, however, that some idea of its character may be gained from the titles of chapters given above, and the following points, taken at random, will serve to illustrate some of the new observations made as well as the carefulness with which cases have been studied. The author has observed hemianopsia in two cases of infantile spastic hemiplegia. Both patients had reached adult life, and the hemianopsia had existed seventeen or eighteen years. In one, the hemiopic pupillary reaction was present. Hemianopsia has not been noted in any of the recent contributions to the literature of infantile cerebral palsy (Osler, Sachs, and Peterson), although these authors together describe nearly three hundred cases. They could not have examined the patients for that condition, for, had this been done, undoubtedly many would have presented this symptom.

Professor Henschen also relates three or four cases of homonymous hemiopic hallucinations, such as were recently described in this Journal, but occurring with hemiplegia and hemianopsia, and not with insanity.

The microscopical observations in this work are based upon the laborious examination of some 10,000 specimens.

In point of typography and lithography, the volume is a rare specimen of book-making. The second volume is to appear shortly. The whole work is one that no neurologist can afford to be without, and every ophthalmologist should be the possessor of this first volume.

It is needless to say that such a work could hardly be published at private expense, and it reflects credit upon the Swedish Government and the University of Upsala that they should have contributed a sum sufficient to make its appearance possible.

Dust and its Dangers. By T. Mitchell Prudden, M. D., etc. New York: G. P. Putnam's Sons, 1890. Pp. 111. [Price, 75 cents.]

If this volume meets with the popularity it deserves, not only will it be a source of profit to its publishers and of increased reputation to its able author, but—more important—it will exercise an influence in domestic administration that will be advantageous to the entire community.

A comprehensive review of the biological character of dust, both out of doors and indoors, leads to the consideration of its real significance in relation to disease, and especially to consumption. With trenchant pen the author deals with the dust dangers of public streets, buildings, and conveyances, and the comparison of the sanitary activity displayed when yellow fever, small pox, or Asiatic cholera threatens a community, with the indifference constantly shown toward consumption is vividly depicted in the sentence, "yet the number of victims of these occasional and dramatic epidemics is quite insignificant as compared with those of our omnipresent consumption."

Of the measures preventive against dust, suffice it to say that Dr. Prudden believes that, as Opies's success with colors consisted in mixing them "with brains," so "with brains" must the dust question be disposed of.

The excellent illustrations drawn by the author are quite valuable in emphasizing the teaching of the book, that can not fail to be as valuable to the professional as to the lay reader.

Medical Diagnosis, with Special Reference to Practical Medicine. A Guide to the Knowledge and Discrimination of Diseases. By J. M. Da Costa, M. D., LL. D., Professor of Practice of Medicine and of Clinical Medicine at the Jefferson Medical College, Philadelphia. Illustrated with Engravings on Wood. Seventh Edition, revised. Philadelphia: J. B. Lippincott Company, 1890. Pp. 16–17 to 995. Price, $6.]

That this work has gone through six editions is sufficient evidence of the value placed upon it by the medical profession. And, while this present edition is an improvement upon its predecessors, it is not quite so thorough as the most popular text-book on the subject should be. For instance, there is no description of the manner in which the ophthalmoscope or the stomach tube is to be used—a deficiency that is manifested when the careful description of laryngoscopic methods is read. Again, in such matters as the method of detecting the Argyll Robertson pupil, and in the methods of discovering the different pathogenic bacteria, there is a paucity, if not omission, of detail that is possibly due to the author's assumption that most of his readers are as familiar with these matters as he is.

In the chapter on examination of the blood Hayem's latest researches have been incorporated; but the consideration of the examination of the blood, as in relapsing and malarial fevers, is not so complete as it should be.

We note these deficiencies as indicating a weakness in what would otherwise be the best work on medical diagnosis in the English language. Accustomed as we are to the excellent index in most of our medical works, the omission of references to subject-matter in this volume suggests that the index has been completely forgotten.

Original Contributions to Ophthalmic Surgery. By J. R. Wolfe, M. D., F. R. C. S. E., Professor of Ophthalmology in St. Mungo's College, Senior Surgeon to the Glasgow Ophthalmic Institution. With Illustrations. London: J. & A. Churchill, 1890. Pp. 2 to 97.

This little work is a brief abstract of clinical demonstrations in ophthalmic subjects, in three chapters, the first being devoted to cataract extraction. Dr. Wolfe regards the use of cocaine as detrimental to union after section of the cornea, as it deprives the tissue of the necessary vitality for adhesion to take place. His operations for cataract extraction are always preceded by iridectomy. This is contrary to the present practice of many ophthalmologists, who think that the perfection of the operation is in securing the round pupil. His treatment of de-

tached retina does not differ materially from that practiced by the American operators. A short chapter is given on plastic operations and skin-grafting. The point made is that a pedicle is not at all necessary to the vitality of a flap or graft, and that the typical graft, either large or small, is to be thin and entirely devoid of areolar tissue. It is difficult to understand how the author could have imagined that such an effort was essential to the progress of ophthalmology.

A Treatise on Massage, Theoretical and Practical; its History, Mode of Application and Effects, Indications and Contra-indications, with Results in over Fifteen Hundred Cases. By Douglas Graham, M. D., Fellow of the Massachusetts Medical Society, etc. Second Edition, revised and enlarged. New York: J. H. Vail & Company, 1890. Pp. x–342.

The author considers the freedom with which his book has been quoted and stolen from on both sides of the Atlantic in a certain sense highly complimentary. Two new chapters have been added—one on local massage in local neurasthenia, and the other on the treatment of scoliosis by means of massage. Attention is called to the fact that the motor points which give the best contraction to faradization are the same that give the best contraction to percussion. There are chapters on the history of massage, its method of application, its physiological effects, and its use in disease of the nerves, muscles, internal organs, and articulations, together with numerous histories of cases treated and the results obtained, all of which is interesting and suggestive reading.

Lectures on Massage and Electricity in the Treatment of Disease (Masso-electrotherapeutics). By Thomas Stretch Dowse, M. D., Fellow of the College of Physicians of Edinburgh, etc. New York: E. B. Treat & Company, 1890. Pp. xix–379. [Price, $2.75.]

The fifteen chapters of this book are devoted to the principles of massage, the mode and method of applying massage, massage of the head and neck, massage and induction, faradaic massage of the skin, massage of muscle and nerve, massage of the venous and lymph circulations, the Weir Mitchell treatment, massage of the chest and abdomen, massage in nervous exhaustion and hysteria, massage of the spine and back, massage in joint and bursal affections, massage in sleeplessness, pain, dipsomania, and melancholia, massage in the wasting diseases of children, and in the diseases of sedentary, changing, and advanced life, electro-physics, and electro-therapeutics. The value of mechanical measures is becoming thoroughly recognized in England and America. In Germany it has long been held in high repute for the treatment of chronic disease. To redeem all mechanical measures from the hands of the charlatan is one of the present offices of the physician. What has been so ably done in behalf of electricity a book like the one under consideration helps to do for massage. The illustrations are excellent guides and the whole work is practical and suggestive.

Transactions of the Royal Academy of Medicine in Ireland. Vol. VII. Edited by William Thomson, M. A., F. R. C. S. Dublin: Fannin & Co., 1889.

This volume is of the same excellence as its predecessors, and the Academy of Medicine in Ireland is to be congratulated on the material that its Fellows bring for its consideration. The papers are arranged as medical, surgical, obstetrical, pathological, hygienic, anatomical, and physiological. As the latest paper was read in the spring of 1889, it will be noticed that this Academy suffers from the misfortune of most societies in publishing its volume when active interest in the subject-matter is cold. Another feature is the omission of any discussion on the papers, and we can hardly believe that they were not worth discussing.

The Medical Student's Manual of Chemistry. By R. A. Witthaus, A. M., M. D., Professor of Chemistry and Physics in the University of the City of New York, etc. Third Edition. New York: William Wood & Co., 1890. Pp. xii–528.

This standard work is too well and favorably known to our readers to make any extended review necessary. In consonance with the original plan of the volume, additions have been made to the chapters on chemical physics, mineral chemistry, and the chemistry of the carbon compounds, so as to introduce the latest discoveries on these subjects, and so retain the *Manual* in the foremost rank of medical text books.

Text-book of Materia Medica for Nurses. Compiled by Lavinia L. Dock, Graduate of the Bellevue Training School for Nurses, Superintendent of Grace Memorial House. New York and London: G. P. Putnam's Sons, 1890.

The name of this work indicates its object—to furnish a text-book of materia medica which will include the points that a nurse needs to know, and exclude the portion which is of use solely to the medical profession. The outlines followed are those taught in the Bellevue Training School, and include something of the source and composition of drugs, their physiological actions, the signs which indicate their favorable or unfavorable action, the symptoms produced by poisons, with their antidotes, and practical points on the administration of medicines. It is written very concisely, and little can be found in it to criticise unfavorably, except the inevitable danger that the student will imagine after reading it that the whole subject has been mastered. The subject of therapeutics has been omitted as not a part of a nurse's study, and this omission is highly to be commended. It will prove a valuable book for the purpose for which it is intended.

A Treatise on the Diseases of Infancy and Childhood. By J. Lewis Smith, M. D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College, etc. Seventh Edition, thoroughly revised. With Fifty-one Illustrations. Philadelphia: Lea Brothers & Co., 1890. Pp. xiv–33 to 900. [Price, $4.50.]

Among the physical disorders treated of in this new edition of Dr. Smith's valuable work on children's diseases not mentioned in earlier editions, are conjunctivitis, icterus, sepsis, umbilical diseases, hæmatemesis, melæna, sclerema, œdema, and pemphigus of the new-born. Epilepsy, tetany, appendicitis, typhlitis, and perityphlitis also receive attention. Dr. Joseph O'Dwyer contributes a paper on intubation of the larynx. All the important pertinent facts that modern research have brought to light are embodied in the present volume, thus bringing it up to date and giving it the dignity of ultimate authority upon the subjects of which it treats.

Epilepsy; its Pathology and Treatment. Being an Essay to which was awarded a Prize of Four Thousand Francs by the Académie Royale de Médecine de Belgique, December 31, 1889. By Hobart Amory Hare, M. D., Clinical Professor of Diseases of Children and Demonstrator of Therapeutics in the University of Pennsylvania, etc. Philadelphia: F. A. Davis, 1890. Pp. 228.

The author states that this essay upon epilepsy was considered by the Royal Academy of Medicine in Belgium as worthy

of a prize of four thousand francs. This is sufficient reason for its present appearance in book form. It is representative of the present views concerning the pathology and treatment of epilepsy, and, if there is nothing new in the two hundred and twenty-eight pages, it is because nothing new concerning the disease and its treatment is definitely known.

Practical Sanitary and Economic Cooking adapted to Persons of Moderate and Small Means. By Mrs. Mary Hinman Abel. The Lomb Prize Essay. Published by the American Public Health Association, 1890. Pp. xi–190.

This is a new-fashioned cook-book compiled with reference to physiology. The dietaries are arranged to give the proper proportion of proteid, carbohydrate, and hydrocarbon in the daily food of all who desire the best nourishment for little money. There is an introduction explaining food principles, and there are chapters devoted to methods of cooking meat, vegetables, and the cereals, cookery for the sick, and bills of fare of the first, second, and third class, with the cost given. The little book contains much information of value. The great problem is to get the class for which it is intended to read it.

Ointments and Oleates especially in Diseases of the Skin. By John V. Shoemaker, A. M., M. D., Professor of Materia Medica, Pharmacology, Therapeutics, and Clinical Medicine, and Clinical Professor of Diseases of the Skin in the Medico-chirurgical College of Philadelphia, etc. Second Edition, revised and enlarged. Philadelphia: F. A. Davis, 1890. Pp. ix–298.

During the past ten or fifteen years the oleates have been prescribed with considerable advantage. Since the appearance of the first edition of Dr. Shoemaker's book in 1885 there has been marked improvement in the quality of preparations of oleic acid and its salts. The author has aimed to make a complete survey of fatty substances as applied to the human body, and has extended the scope of the present work so as to include a consideration of ointments. The official lists of France, Germany, and Austria, together with those used in Italy, Spain, and the Spanish colonies, have been compiled from all accessible sources. And thus *Ointments and Oleates* serves as a conspectus of the whole subject of inunction.

BOOKS AND PAMPHLETS RECEIVED.

Rhinoplasty. Being a Short Description of One Hundred Cases treated by Tribhovandas Motichaud Shah, L. M., Assistant Surgeon and Chief Medical Officer, Junagadh. At the Junagadh Hospital. With Illustrations and Remarks. Printed at the Junagadh Sarkari Press, 1889. Pp. 130.

One Hundred Consecutive Cases of Cataract, operated upon by T. M. Shah, L. M., etc.

On the Treatment of Eczema in Elderly People. By L. Duncan Bulkley, A. M., M. D., New York. [Reprinted from the *Transactions of the Medical Society of the State of New York.*]

Reports on the Progress of Medicine.

DERMATOLOGY.

By GEORGE THOMAS JACKSON, M. D.

Oleum Physeteris seu Chænoceti is the euphonious title of a vehicle for skin medication introduced to us by Dr. Guldberg, of Copenhagen (*Monatshft. f. prkt. Derm.*, 1890, vol. x, No. 10). To most of us it sounds as strange as the Syrian tongue, though we feel a little encouraged when we note that one of its synonyms has the good English ring of "bottlenose oil." As a matter of fact, it is a species of whale oil taken from a whale that is found in the fjords of Norway, whose scientific name is *Balæna rostrata*, or *Hyperodon rostrata*. The oil has a remarkable penetrating power, as proved by experiments. It was found to pass through the human skin in eight hours by simply resting in contact with it, while olive oil did not so pass in twenty-four hours. It contains a large amount of stearin and readily saponifies. Its specific gravity is less than that of other animal oils. It would seem to promise well as a means of lubricating the skin, and of causing medicinal substances to penetrate the skin. It combines readily with various medicines, such as chloroform, carbolic acid, mercury, lead, salicylic acid, sulphur, naphthol, aristol, iodoform, and iodine. We are promised a future paper upon the subject. In the mean time the above-mentioned substances have been used in various combinations with the oil as a vehicle.

Aristol, the much-lauded new drug, is now standing its trial. In the *Ann. de derm. et de syph.*, 1890, No. 7, we find three reports upon it: one by Schirren, from the *Berlin. klin. Wochnsch.*, 1890, p. 252; one by Seifert, from the *Wiener klin. Wochnsch.*, 1890, p. 342; and one by Brocq, from the *Bull. et mém. de la Soc. médic. des hôpitaux*, 1890, p. 350. It was found to be unirritating, slow, but effective in euring psoriasis in ten-per-cent. strength (Schirren and Seifert). In lupus it was useless in three cases (Schirren and Seifert), and curative in one case (Seifert). It proved curative for ulcers of the leg and tertiary syphilitic ulcers (Seifert and Brocq), for epitheliomatous ulceration (Brocq), and mucous patches (Seifert). It helped one case of eczema intertrigo, and greatly irritated one of seborrhœal eczema (Seifert).

Another Method of using Resorcin in Skin Diseases is proposed by Dreckmann (*Monatshft. f. p. Dermat.*, 1890, No. 9, p. 389) and is as follows: The diseased part is covered with a layer of linen or lint saturated with an aqueous solution of resorcin of one- to three-per-cent. strength, and this is covered by an impermeable bandage of oil-cloth (?) or rubber. It acts by macerating the part, since it keeps it in a moist heat; it protects it from injury; and it hastens the cornification of the epithelial cells on account of the resorcin. It has proved useful in moist eczemas of children, but is to be discontinued when the moisture diminishes. It is then to be followed by mild lead, zinc, or sulphur ointments. Hyperplastic thickenings of the skin resulting from chronic eczema, such as of the scrotum, do well up to a certain point, when other means must be used to complete the cure. [It is a question whether the resorcin has any action in the improvement effected by this dressing. We certainly have obtained more brilliant results in similar cases by the use of rubber alone, either with or without the interposition of a piece of linen between the bandage and the skin.]

The Elimination of Iodide of Potassium by the Kidneys has been studied by Dr. Ehlers, of Copenhagen (*Annal. de derm. et de syph.*, 1890, 1, 383). He finds that, on account of the rapid absorption and elimination of the iodide, there is little danger of intoxication by it, even in large doses, so long as the kidneys remain sound. All cases of intoxication by the iodide have been in patients with diseased kidneys, and in them it is found that symptoms of iodism showed themselves when only half of the amount taken was excreted by the kidneys. Under normal conditions, when the patient is taking 20 grammes (about 300 grains) of the iodide during the day, the urine will contain the salt in the proportion of about seventy-five to eighty parts in one hundred of urine. If more than this amount is taken, absorption seems to be incomplete. All the ingested salt seems to be eliminated, no matter what the amount taken, within four or five days after stopping the drug. The only objection our author sees to the administration of large doses of the iodide to patients with normal kidneys is its cost. But he makes the novel suggestion that this expense may be reduced by gathering the urine from these patients and from it making fresh iodine!

Pigmentation of the Human Skin.—Philippson, of Hamburg, has studied with care the subject of pigmentation of the human skin, and now (*Fortschritte d. Med.*, 1890, viii, 216) gives us the conclusions he has arrived at from his observations. He thinks that there is a differ-

ence between the human skin and that of salamanders and frogs that was studied by Ehrmann, in that the chromatophores of the latter are in the human subject replaced by the "mast" cells of Ehrlich, the plasma cells of Waldeyer. These form a chain around the blood-vessels, follow the capillaries into the papillæ, and sooner or later join the pigment cells. Our author thinks that certain cells take from the blood a colorless granular material, which they pass on from cell to cell. Gradually this material in its passage becomes changed to pigment, and at last is deposited in the tissues. Thus far no explanation is forthcoming of *how* the "material" is taken out of the blood and changed into pigment. Though this theory can not be anatomically demonstrated, it is considered to be justified by the following facts: 1. At the border line where "mast" cells and pigment cells are found together in the heaps of pigment granules a few "mast"-cell granules are found, and also among the mast-cell granules a few pigment granules are found, or two collections of pigment granules are connected by means of mast-cell granules. 2. In the white mouse there is absolutely no pigment. In the deeper layers of its skin the mast cells are seen full of granules, while in the papillary layer of the skin they have very few granules. In the gray mouse pigmentation is but slight, and in them the mast cells have likewise little pigment in the papillæ. 3. In the human skin the pigment cells are placed in rows into which mast cells are frequently inserted. 4. In many preparations the mast cells are found between the epithelial cells. 5. In the skin of the black paws of the guinea-pig there are hardly any pigment cells, but mast cells. 6. In the adder's embryo there are colorless cells that correspond to the mast cells, and these at first are in the lower layers of the epidermis. They seem to have some close relation to the pigment formation.

The Pathogeny of the Cutaneous Lesions is the title of a suggestive article by M. Jacquet in *Annales de dermatologie et de syphiligraphie*, 1890, i, 486. His idea is that a great variety of cutaneous lesions may be depeudent upon the same underlying cause—a vaso-motor disturbance; and that many of our supposed distinct diseases of the skin are not really such, but merely forms of manifestation of the same disease—a neurosis. He thus would find a close relationship, if not identity, between urticaria and lichen ruber, and holds both as being purely due to an external irritation, so far as the lesions are concerned. He points out that the pruritus is the first symptom in both diseases; that this induces the scratching, which in one disease is followed by wheals and in the other by an eruption of acuminated papules. The external origin of many skin lesions is, he believes, demonstrated by the simple experiment of wrapping a tumefied part tightly in a dry bandage, when the swelling will completely disappear. He did this in an undiagnosticated case of tumefaction of the skin which had lasted more than a year, and saw the part return to its normal color and size in less than ten days. He believes that the same nervous disturbance will produce now one lesion and now another, according to whether the vaso-motor influence acts on the arterial or venous capillaries or the lymphatics, and according to the condition of the walls of the vessels themselves. As to the cause of the vaso-motor disturbance we are still in ignorance. As a working hypothesis, we may suppose that it is a toxine secreted in the organism by pathological or non-pathological microbes acting upon a nervous system disturbed by a moral shock, alcoholism, excesses, fatigue, and the like.

A Case of Stigmata is reported by P. Ferroud in the *Loire médicale*, March 15, 1890, in the person of a prostitute, eighteen years old, who was hysterical. The hæmorrhages took place from the nasal and conjunctival mucous membranes, the external auditory canals, and the skin of different parts of the body. They appeared most frequently one or two days after the cessation of the menses, and lasted one or more weeks. They began like little vesicles or slight elevations, and with a dull pain. The affected area slowly spread.

Lupus of the Extremities, according to Dr. F. Hahn (*Archiv f. Derm. u. Syph.*, 1890, xxii, 473), is met with very frequently in the clinic of Professor Doutrelepont, of Bonn, no fewer than one hundred and five cases having been entered there from June, 1882, to January, 1890. These formed 24·5 per cent. of the entire number of lupus cases. Fifty-eight of them occurred in males and forty-seven in females. In forty-nine of the cases the original location of the disease was on the extremities, while in forty-four it was first seen on the face, in nine on the neck, and in three on the trunk. In only eight cases was the disease on the extremities the only symptom of tuberculous disease. In the rest there were evidences of enlarged glands, diseased lungs, or hereditary tubercular tendency, and in two cases the mothers had lupus. In more than one quarter of the cases (26·6 per cent.) the disease began before the fifth year of life. The upper extremities were affected fifty-five times, lower extremities thirty-two times, and the upper and lower extremities together eighteen times. The extensor surfaces were much more often affected than the flexor surfaces. In fourteen cases there were only old lupus scars; in thirty-nine, lupus serpiginosus; in fourteen each, lupus vulgaris, exulcerans, and hypertrophicus; and in twelve cases lupus papillosus. Under the last division are included cases of tuberculosis verrucosa cutis, which is regarded as unworthy of a separate title, its only distinguishing feature being its superficiality. Lupus caused very little interference with the functions of the limbs, excepting in cases where it was very widely distributed and produced very extensive scars. Occasionally when the lupus process surrounds the limb, or nearly so, and begins to cicatrize in some places, the pressure from the cicatrix will give rise to obstruction of the circulation, to an œdematous state, and finally to a condition of the extremity like elephantiasis, and sometimes requiring amputation for relief. Caries of the joint may likewise give rise to interference with the function of the limb.

Tuberculosis Verrucosa Cutis is the subject of a contribution to the *Archiv für path. Anat. und Phys. und für klin. Med.*, 1890, Heft 3, by Dr. Brugger, of Würzburg. In his case the disease was located on the right leg of a man twenty-two years old, of healthy parentage, and had existed since his third or fourth year of age. Apart from the skin lesion, the man was in good health. The affected leg was covered with a number of cicatrices and appeared somewhat thickened, and its skin felt hard and leathery. Over the tendo Achillis and on the back of the foot there was a recent bluish-red cicatrix, in the neighborhood of which were scattered numerous large and small elevations of the skin. Along the side of the foot there were three ulcerations with broad bases and overhanging edges. On the inner side of the thigh there were several old cicatrices and one recent one. Sections from the new lesions contained tubercle bacilli, and inoculation experiments upon a guinea-pig were successful, the animal dying of tuberculosis within six weeks. Brugger believes that this is the first time that an attempt has been made to inoculate an animal with a piece of a lesion of tuberculosis verrucosa cutis, and that the positive result is of great value in deciding the nature of the disease. It is to be diagnosticated from lupus by an absence of the characteristic lupus tubercles, by its having no disposition to return in the cicatrices, and by being more superficial. Otherwise their course is very much alike. From syphilis the diagnosis is made by an absence of the infiltrated wall and dirty brown-red color of the syphilitic ulcer, by its much more chronic course, and by the more deforming cicatrices that it leaves. It is probable that the so-called verruca necrogenica is the same as tuberculosis verrucosa cutis. Why infection of the skin by the tubercle bacillus should at one time produce lupus, at another time a tuberculous ulcer, at another time verruca necrogenica, and at yet another time tuberculosis verrucosa cutis, is a yet unanswered question. It is probable that individual peculiarities have something to do with it. The virulence of the poison may also play a part in determining the nature of the lesion. It is possible to have a general infection of the system follow a local infection, though this is exceptional. This event may take place either through the lymphatics or through the blood.

The treatment must be by destruction of the lesion by excision, by scratching out with the curette, by caustics, or by a combination of either of the first two methods.

Keloid forms the subject of an interesting study by Leloir and Vidal (*Annal. de derm. et de syph.*, 1890, No. 3). They follow the usual division into two varieties—the true keloid, primary, developing spontaneously, and rare, which they name the spontaneous keloid; and the false keloid, secondary to a pre-existing cicatrix, which they denominate the cicatricial keloid. Symmetry in development is regarded by them as characteristic of the true keloid. The growths enlarge with more or less rapidity till they attain to a certain size, when they remain stationary. Rarely do they undergo spontaneous diminution in size. Sometimes

they form bands or cushion-shaped or claw-shaped figures; sometimes they form flattened, convex, or slightly concave plates; sometimes they are quadrilateral, or oval, or crab-shaped. Superficially the skin seems of normal consistence, the glandular orifices being preserved and the hairs not destroyed, though they are generally of the lanugo variety. The new growth is located in the corium, so that the epidermal layer is intact; and, as it never goes beyond the thickness of the skin, the tumor is always freely movable upon the underlying parts. The thickness of the new growth is as much as 15 mm. at times (about five eighths of an inch). The color is rosy, sometimes with teleangeiectases over the surface of the tumor and at its periphery. The color may be deeper at one time than at another, and menstruation is said to have the effect of darkening the color. The tumors are firm and elastic, indolent or painful on pressure or spontaneously. True keloids are more numerous in the same subject than the false variety and do not reach so great a size as a rule. There is a predisposition to these growths inherent in the skin of those who are subject to them. Microscopical examination of the tumors shows that the epidermis, interpapillary prolongations, and papillæ are of normal appearance, and this at once distinguishes the true from the false keloid. The true keloid is located in the corium. In its center there are no glands, but in the upper and lower part of it we find strangulated hair follicles and flattened and altered sebaceous and sweat glands, which become of more and more normal appearance as we approach the periphery of the tumor. No alteration of the nerves has yet been found. The tumors often seem to stand in relation to an altered sebaceous gland, and it may be that they take origin in an acne pustule.

The false or cicatricial keloid is not identical with the hypertrophied cicatrix. It arises secondary to some injury, no matter if even so slight a one as the prick of a pin, in a predisposed individual. It is specially prone to follow a deep injury or a burn. It may not begin for years after the injury, but it always begins in a cicatrix. If several scars are, present on the same part, all are not affected. As in the true keloid, the sites of predilection for the tumors are the sternal and mammary regions, the shoulders, the posterior part of the neck, the buttocks, the arms, and rarely the legs. They rarely appear during old age. The size of the tumor is in no sort of proportion to the extent of the injury. It grows rather faster than the true keloid, and exceeds the limit of the original cicatrix, in this differing from the hypertrophied scar, which does not advance beyond the borders of the cicatrix. Its surface is mother-of-pearl-like, shining, smooth, without any sign of papillæ glandular orifices, hair, or lanugo. As it enlarges, the outer parts are less altered in appearance. The hypertrophied scar does not go beyond the original loss of substance, is redder, more vascular, and softer than the keloid, and has no prolongations into the sound skin; it usually is painless, and sometimes terminates by resolution.

The treatment that, according to our authors, is the most to be relied on is by multiple scarifications. These are to be made at two millimetres' distance from each other and crossed in such a way as to describe square or lozenge-shaped figures on the skin, deep enough to reach almost to the depth of the tumor, and long enough to just go beyond its borders. Before scarifying, the part must be anæsthetized. There is but little loss of blood, and the bleeding is soon and easily checked. Immediately after the operation the part is to be dressed with boric acid and the next day covered with mercurial plaster, which is changed every morning and evening. These scarifications are to be repeated until the growth disappears, which, it is said, it will do.

A Case of Congenital Alopecia is reported by Dr. P. de Molènes in *Annales de dermat. et de syph.*, 1890, i, 548. The patient was a girl whose mother had had an attack of alopecia areata when she was nineteen years old, and whose brother had gone through the same experience when he was six years old. In the mother and the boy the disease was promptly mastered. The little girl was born so long after the others had recovered that contagion could not be thought of as a cause. The child was born with an almost imperceptible down upon the scalp, no eyebrows, hardly visible eyelashes, and well-developed nails. Upon the nape of the neck and occiput there was a series of very minute vascular nævi. The child was robust, well developed, and lively. At five months of age the rudimentary eyelashes fell out, and the scalp became white and smooth. At sixteen months of age a hand-glass showed the hair follicles of the skin to be open, but no sign of hair. There was no keratosis pilaris. Dentition was normal. Under stimulating treatment with soap frictions, ointments, and alcoholic lotions of various sorts, the hair gradually grew in during three years, so that all the scalp was covered but a small piece behind the left ear. The growth did not begin until after a year and a half of active treatment. There were no characteristic lesions in the hair, and there were no parasites. The case was probably dependent upon a nervous cause—a trophoneurosis inherited from the mother.

Alopecia Neurotica.—The advocates of the neurotic origin of alopecia areata will find comfort and support in an article by Askanazy in the *Archiv f. Derm. u. Syph.*, 1890, xxii, 523. He cites two cases from Professor Michelson's clinic in Königsberg. In one, that of a man thirty-one years old, the hair-fall was upon the right side and followed a facial paralysis of the same side consequent upon the removal of a tumor from the right submaxillary region. He also had hyperidrosis of the right side. The scalp was normal. In the second case the baldness occurred upon the face, temples, and pubes. The patient was melancholic and hypochondriac, and suffered from severe headache, burning of the top of the head, and insomnia.

Epidemic Zoster forms the text for a discourse by Dr. Weis, of Prague (*Archiv für Derm. und Syph.*, 1890, xxii, 609), in which it is attempted to be proved that because zoster occurs not infrequently in an epidemic manner, which nobody can deny, therefore it is an infectious disease, which seems hardly proved as yet. The strongest part of his thesis is that in which the theory of one Pfeiffer is overthrown. The theory is that the lesions of zoster are located along the arterial branches supplied to the skin, and not, as before believed, along the distribution of the cutaneous nerves. This theory our author completely upsets, which leaves us still free to believe in the nervous origin of the lesions, whatever we may regard as the chief ætiological factor in the disease.

The Pathological Anatomy of Psoriasis has been studied once again—this time by Dr. E. Kromayer, of Halle (*Archiv f. Derm. u. Syph.*, 1890, xxii, 557). Before proceeding to the demolition of various other theories in regard to this interesting subject, all of which have been based upon more or less careful studies of microscopical preparations by competent observers, he has a few words to say about the heretofore usual division of the skin into three layers—viz., epidermis, cutis vera, and subcutaneous tissues. He says that this is wrong, histologically, physiologically, and pathologically. Histologically, the upper vascular layers of the skin are entirely different from the rest of the skin, not only in regard to the connective tissue proper to it, but also as to its blood-vessels, lymphatics, and nerves. Physiologically, the papillary layer of the cutis belongs to the epidermis, being its nutritive layer. Its only relation to the rest of the cutis vera is that through the latter run the blood-vessels and nerves that are supplied to it. Regarding the skin as an organ proper, then, the epidermis would represent the parenchyma, while the papillary layer would be the interstitial tissue. Together they form an organ in whose physiological functions the cutis vera takes no part. Pathologically, the union of the epidermis and the papillary layer of the skin is evidenced by the common division of inflammatory skin diseases into superficial (those affecting the papillary part of the skin) and deep (those affecting the cutis vera and the subcutaneous tissue). Further, as we know that in certain parts of the skin the papillæ are entirely wanting, it would be best to give this layer a new name, and designate it as the *cutis vasculosa*. Inasmuch as it is desirable to employ some system of naming the parts of the skin to show that it is a parenchymatous organ similar to the kidneys, etc., the following is proposed, namely: 1. Cutis parenchymatosa, consisting of two parts—the epidermis and cutis vasculosa. 2. Cutis vera. 3. Subcutaneous connective tissue or hypoderm.

He now proceeds to an examination of the skin upon this basis of histological division. The study is far too long for us to give it in detail here; we can only give his conclusions: He finds the changes in the epidermis to consist in (1) a proliferation of the epidermis or of its epithelium; (2) a permeation of the epidermis with round cells which are heaped up under the horny layer in places; (3) an irregular formation of the stratum granulosum. As to the process of cornification of the epidermic cells, he says that a normal cornified cell consists

of a cornified cell mantle and of protoplasmic cell contents which, with the exception of the nuclear cavity, are entirely without structure. The cells of the rete Malpighii possess a cell membrane, which increases in thickness and solidity the nearer we approach the horny layer. These cell membranes show the same physiological behavior as the corneous membranes—that is, they are transformed into large vesicles by the swelling of their cell contents. They have the same chemical reactions, resisting the action of potash, hydrochloric acid, and digestive agents, and differing from them only in that their powers of resistance are somewhat less. They are, therefore, corneous membranes in a young and tender state. The process of cornification is then a gradual and even progress through the whole thickness of the epidermis from below up to the horny layer, consisting in an ever-increasing thickening and solidification of the cell membrane. He regards the kerato-hyalin as only the histological expression of the necrobiosis of the cells of the epithelium.

His conclusions from his studies are as follows: Each efflorescence of psoriasis begins with a hyperæmia of the cutis vasculosa, to which an infiltration of cells is added. Soon after and coincidently with these changes an intense proliferation of epithelium takes place. The cutis vasculosa and the epidermis increase at the same time, and together form a thick papillary body; the cutis parenchymatosa is hypertrophied. During these changes numerous migratory cells have permeated the epithelium and disturbed the normal cornification; thus are formed the psoriatic scales in layers. The primary changes are, therefore, in the cutis vasculosa. These are not of an inflammatory nature, as there are lacking the five cardinal symptoms of the same—namely, "ruhor, tumor, calor, dolor, functio læsa." There are also wanting fluid exudation, pustulation, granulation, and cicatrization. The process is not inflammatory. It is to be regarded rather as a progressive disturbance of nutrition, an hypertrophy of the parenchymatous skin in which the peculiar and characteristic formation of scales is due to an interference with the normal formation of the corneous layer by the migration of cells into the epithelial layer of the skin.

The ætiology of the disease is still a matter of doubt, no one of the theories (parasitic, dyscratic, idiosyncratic, or neuropathic) being satisfactorily proved. The only sure thing is that the parasite which causes, or may be the cause of, the disease is not a superficial one.

Seborrhœal Warts form the subject of a study by S. Pollitzer (*Monatshft f. prakt. Derm.*, 1890, xi, 145). As it emanates from Unna's laboratory, we are probably justified in reading "Unna" written between the lines. The malady appears most often in old people, and takes the form of more or less numerous, slightly elevated, round or oval, light-fawn to black-colored spots on the skin. These appear most frequently on the middle of the back, the lower half of the abdomen, the sternal region, and the anterior and lateral surfaces of the lower half of the neck. They frequently group themselves. In size they may be no bigger than the head of a pin, or they may attain the diameter of a twenty-five-cent piece. Histologically, they consist in a somewhat thickened stratum corneum and a markedly hypertrophied rete Malpighii; they show epithelioid cells in the papillary and subpapillary layers of the skin, which are arranged in groups and lines and separated from each other by connective-tissue fibers; a marked infiltration of fat pervades the epithelium of the neighboring sweat glands, the middle and papillary layers of the cutis, and the epithelium of the rete; finally, there is atrophy of the sebaceous glands and the hair follicles. They are considered to belong to the order of lymphangeiofibroma.

The Treatment of Trichophytosis Capitis and of Favus is discussed by A. Bertarelli in the *Bolletino della Poliambulanza di Milano*, 1890 (*Ann. de derm. et de syph.*, 1890, i, 596). He prefers the use of the pitch plaster to all other methods, and declares that patients find this manner of epilating much less painful than that with the forceps. It clears the scalp of hair much more effectively than the pinchers, and absolutely prevents self-inoculation. His plaster is composed of thirty parts of Burgundy pitch (résine de pin), eight parts of black pitch (pix navalis), two parts of Venetian turpentine, and one part of lard, spread upon small strips of linen. The crusts and scales are first removed from the scalp by the free use of grease and lead plaster, and then the strips of pitch plaster are applied. They are raised one by one after a day or two, and any hair that has escaped the plaster is to be removed with the epilating forceps. The scalp is then either washed with soap and water or bathed with a bichloride-of-mercury solution or Lugol's solution. Then the pitch plaster is reapplied, each time a more extensive area of the scalp being covered until the whole is enveloped in a true skull-cap. Thus the patient is gradually accustomed to the treatment, which must be continued for a varying number of months, say six to eight for favus and six to twelve for ringworm.

A Case of Syphilitic Infection of a Wife by her Husband Four Years and Nine Months after the Appearance of the Chancre has been reported by Charles Mauriac to the French Society of Dermatology and Syphilis (*Ann. de derm. et de syph.*, 1890, 1, p. 575). There was no reason to suspect that the woman came by her syphilis—a chancre upon the perinæum and a general erythematous syphilide—in any other way than by her husband. The man had been under thorough treatment by Dr. Mauriac from the time of the initial lesion. The infection of the wife took place four years and nine months from the date of the initial lesion of the husband.

Syphilis as an Infectious Disease in the Light of Modern Bacteriology is the long but attractive title to an able article by E. Finger in the *Archiv für Derm. und Syph.*, 1890, Hft. 3, fo. 331. Admitting that hypotheses, not exact knowledge, still prevail in much that is written and said about syphilis, he advances the theory that, besides the specific virus of syphilis, the ptomaine, which is the result of chemical changes caused by the presence of the virus, gives rise to many of the symptoms of syphilis, and is the agent by which many a fœtus becomes infected *in utero*. It is, moreover, the agent that produces immunity to syphilis, such as is seen in women giving birth to syphilitic children, themselves remaining apparently free from the disease, and able to nurse the children without infection. If the ptomaine is present in a certain amount, or the organism of the patient has good powers of resistance, the ptomaine will only protect against infection by the virus, producing immunity. If the ptomaine is present in large amount, or the organism has feeble powers of resistance, then it will give rise to such symptoms as cachexia, loss of hair, and most of the manifestations of the so-called tertiary stage. Such is a brief outline of the author's thesis. Taking up the article in the order in which it is presented, and almost unpardonably condensing it, we note the following as the basis upon which he builds his theory: I. The primary stage of syphilis. The initial lesion and multiple enlargement of the glands are due to the local increase of the specific virus, be this a bacillus or something else. At the same time the presence of the virus gives rise to certain chemical changes, the product of tissue changes, which produce alteration in the connective tissues, and contribute to the hardness of the affected parts. While we do not know the exact time at which the virus leaves the sclerosis and enlarged glands, we are quite sure that the ptomaine very early enters into the blood and lymph circulations and is distributed throughout the body. The amount of the ptomaine increases in geometrical proportion to the increase of the virus, and produces that general intoxication of the whole body seen at this time. At the same time with the general diffusion of the ptomaine through the circulation we have also a diffusion through the tissues in the neighborhood of the initial lesion. As expressions of the intoxication we note: 1. Immunity from further inoculation with the virus. 2. General symptoms, such as anæmia, fever, prostration, weakness, pains in the limbs and joints, albuminuria, icterus, neuralgia, and hyperæmia of the retina, all of which are too ephemeral and unstable to be due to a deposit of the virus itself. The fact that iodide of potassium exerts a healing effect on these symptoms while it has little if any influence upon the sclerosis, and, on the other hand, mercury influences favorably the latter but not the former, shows that there is a different chemical reaction in them, and strengthens the idea that they are due to different causes. II. The secondary stage. The various secondary lesions are due, without doubt, directly to the virus, but the constitutional symptoms are probably due to the ptomaine, as well as the seborrhœa, alopecia, and dryness of the nails. In malignant, precocious syphilis it is probable that the profound intoxication of the system by the ptomaine is responsible for the severity of the symptoms. In the latent period which follows the secondary stage we do not know

what becomes of the virus in those cases in which later symptoms show themselves. Nor do we know when the virus leaves the system in those cases in which complete recovery seemingly takes place. During this period many subjects are not quite in normal condition. The most noticeable fact of this period is—III. The immunity against new infection. How long this immunity may last we do not know. That it probably is in some cases limited is shown by the well-authenticated instances of reinfection. Immunity does not prove that the individuals are still syphilitic any more than the immunity acquired from having had variola indicates that the individual still has variola. This immunity is due to the influence of the ptomaine upon the tissues, and may be acquired without passing through the active stage of syphilis. This is seen in the acquiring of immunity to infection on the part of the mother of a child syphilitic by the father. While it is possible for the virus to pass through the placenta from the fœtus to the mother, it is uncommon. But ptomaines must so pass, and while these are not capable of producing syphilitic lesions, they do render the mother immune to further infection with syphilis. The same thing occurs and produces like results when a healthy child is born to syphilitic parents. IV. The tertiary stage. It is the opinion of the majority of syphilographers that this stage is not the direct result of the syphilitic virus, but a consecutive diathesis, the virus having been eliminated. In support of this opinion we find: 1. The relative rarity of tertiary symptoms. 2. Their late appearance after infection. 3. The difference in the disease picture. 4. The non-contagiousness of the disease at this time. 5. The non-transmissibility of the disease. 6. The possibility of reinfection. 7. The different chemical reaction to mercury and iodine. 8. The fact that tertiary symptoms, like immunity, can occur in individuals who have never shown signs of primary or secondary syphilis. We see this both in the mothers who have gained immunity by carrying syphilitic fœtuses, and in children of syphilitic parents who, though never showing signs of active syphilis, exhibit great disturbances of nutrition, or pure tertiary lesions, late after birth. [The whole paper will well repay perusal, and we commend it to all students of this very interesting disease.]

Miscellany.

Inebriety and Life Insurance.—The American Association for the Study and Cure of Inebriety will hold the first of a series of monthly meetings at the hall of the New York Academy of Medicine, on December 10th, at 8 P. M. The subject of the evening will be presented in papers by Dr. T. D. Crothers, of Hartford, Conn., On Alcoholic Inebriety and Life Insurance, and Dr. J. B. Mattison, of Brooklyn, On Opium Addiction and its Relation to Life Insurance. Other physicians will participate in the discussion, and the medical profession are invited to be present.

Mosquera's Beef Meal is an alimentary preparation put upon the market by Messrs. Parke, Davis, & Co., of Detroit, who state that it represents, in actual nutritive value, at least six times its weight of good lean beef; that it is perfectly palatable, and will be tolerated with ease by the most delicate stomach; that it admits of being administered in a variety of forms, thus avoiding monotony in the food; and that it is the most nutritious as well as the most economical concentrated food.

The late Dr. Emil Neumer.—On November 4, 1890, a joint meeting of physicians and laymen connected with St. Mark's Hospital and the German Poliklinik, respectively, was held at the residence of Dr. Beck, 187 Second Avenue. The late Dr. Emil Neumer had been connected with said institutions for a number of years.

The following resolutions, submitted by a committee, were unanimously adopted:

Whereas, our friend, Dr. Emil Neumer, Supervising Physician of St. Mark's Hospital and a member of the German Poliklinik, has departed this life; and

Whereas, by his untiring zeal and singleness of purpose, he earned the good-will and gratitude of all connected with both institutions; and

Whereas, his self-sacrificing labors contributed largely to undermine his health, be it

Resolved, That the physicians and members of St. Mark's Hospital and of the German Poliklinik, at a special joint meeting assembled, do express their deep sense of grief at the untimely loss of their friend and fellow-worker, Dr. Emil Neumer, and further express their heartfelt sympathy with, and tender their condolence to, his bereaved family; and

Resolved, That a copy of these resolutions be published in the medical journals.

The Committee:

Dr. C. Beck,
Dr. H. J. Boldt,
Mr. F. A. Botty. } *For St. Mark's Hospital.*

Dr. Th. Busche,
Dr. S. Kohn,
Dr. George W. Rachel. } *For the German Poliklinik.*

Dr. H. J. Garrigues, *Chairman.*
Mr. Max Ruttenan, *Secretary.*

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

WHAT INFLUENCE WOULD A MORE PERFECTED OBSTETRIC SCIENCE HAVE ON THE BIOLOGICAL AND SOCIAL CONDITION OF THE RACE?*

BY ALFRED L. CARROLL, M. D.

WHATEVER spiritual sins of mine may be stricken from the books of the Recording Angel, as fully expiated by the penitential attempt to answer the question allotted to me in this discussion, I fear that I shall add to my professional shortcomings in venturing upon an argument which depends almost entirely on an overstrain of the "scientific use of the imagination."

For a proper consideration of the problem we should possess statistical evidence of the mortality and morbility of mothers and children respectively, due, immediately or remotely, to parturition, and of the degree in which such mortality and morbility may be regarded as preventable. This evidence, however, is in all respects scanty, and in some absolutely non-existent.

"Still-births" are not officially registered either as births or deaths, and even in the very imperfect occasional records of them it is impossible to separate the fœtal deaths before the beginning of labor from the deaths during birth or soon after birth, the latter being often reported under this category; nor can we determine, outside of a few hospital reports which represent an infinitesimal fraction of the total child-bearings, the proportions of abnormal presentations, of deformed maternal pelves, or of spontaneous or artificial deliveries in these alleged still-births, the vast volume of private midwifery being virtually a sealed book. Quételet computed the ratio of still-births to total births as 1 in 12·5, or a little over 8 per cent., but he evidently included many children who had breathed before dying, as is demonstrated by the contemporaneous tabulation of Mme. Lachapelle's experience, comprising 22,243 births, with a total mortality of 1,600, being 1 in 13·9, or 7·2 per cent. But of these, 763 were not born dead, 633, or 2·85 per cent. of the total births, being classed as "feeble"—*i. e.*, "apoplectic, premature, etc."—116, or 0·52 per cent., as "abortive" (non-viable), and 14 as monstrous or deformed, leaving 837, or 3·76 per cent., actual still-births. This accords with the few later estimates founded on sufficient numbers to warrant generalization. Farr opined that in England the proportion was about 4 per cent., in Belgium (1860–1865) it was reported as 3·7 per cent., in France (1875) as 3·6 per cent.

There are no means of ascertaining how many of these "dead-born" are done to death during the act of parturition, but that the number is very great may be inferred from a comparison of spontaneous and artificial deliveries, the latter of which are usually performed on account of mechanical obstacles in the genital passages, uterine inertia, maternal hæmorrhage or convulsions; or, on the fœtal side, malpresentations, prolapse of cord or arm, or deformities of various kinds. From the subjoined condensation which I have made of Lachapelle's tables, it is shown that in all the spontaneous deliveries (omitting those of the shoulder, in which the two still-born are specified as "putrid") the ratio of the dead-born is 3·5 per cent., while in the artificial deliveries it rises to 25 per cent.:

PRESENTATION AND DELIVERY.	Total.	Living.	Dead.	Feeble.	Abortive or deformed.	Total deaths.	Excluding non-viable children.
Vertex, spontaneous	20,567	19,450	635	462	20	1,117 = 5·43%, or 1 in 18·4	1 in 18·75
" forceps	72	38	17	17	...	34 = 46·6% " 1 " 2·1	
" version	47	29	8	10	...	18 = 38·3% " 1 " 2·6	
Face, spontaneous	88	78	3	6	1	10 = 11·36% " 1 " 8·8	
" forceps	5	1	1	3	...	4 = 80·00% " 1 " 1·25	
" version (inertia)	7	4	...	3	...	3 = 42·86% " 1 " 2·33	
Pelvic, spontaneous	790	575	101	98	16	215 = 27·2% " 1 " 3·67	1 in 3·9
" version	12	6	3	3	...	6 = 50·0% " 1 " 2	
Shoulder, spontaneous	12	....	2	...	10	12 = 100%	
" version	106	63	26	17	...	43 = 40·57%, or 1 in 2·5	
Brow, changed to face	2	1	...	1	...	1 = 50·0%	
Craniotomy	12	....	9	...	3	12	
Hysterotomy, after death of mother	4	....	2	2	...	4	
Presentation undetermined, spontaneous	517	397	29	11	80	120 = 23·2%, or 1 in 4·3	1 in 12·9
" " version	2	1	1	...	...		
Total spontaneous	21,974	20,500	770	577	127	1,474 = 6·7% " 1 " 14·9	1 in 16.3
" artificial	269	143	67	56	3	126 = 46·8% " 1 " 2·13	1 " 2·19
" spontaneous and artificial	22,243	20,643	837	633	130	1,600 = 7·19% " 1 " 13·9	1 " 15·13

Further analysis of the presentations and accidents of labor is necessary to gain a partial view of the cases in which obstetric science and art may lessen this mortality, which means the death, at or soon after birth, of nearly seventy-two thousand children out of every million born.

In the vertex presentations, spontaneously born, of Lachapelle's table, the "dead" were 1 in 32·4, and the "feeble" (dying within a day or two) 1 in 44·4, the only commentary made being that, in ten or twelve instances, the cord was prolapsed, half of these dying during delivery. Of her artificially-aided vertex deliveries, the "dead" were 1 in 4·76 and the "feeble" 1 in 4·4. But in the 72 applications of the forceps, 39 were for uterine inertia or rigidity of the external genitalia, 8 for pelvic contraction, 2 for "scirrhus of cervix," 1 for hæmorrhage, 1 for uterine obliquity, 8 for maternal convulsions, 9 for faulty positions

* Read before the New York State Medical Association, October 23, 1890.

of the head, 3 for prolapse of the cord, 1 for prolapse of arm—that is to say, in 59, or 82 per cent. of the whole, the dystocia was due to maternal causes, the children dead or dying being 1 in 2·1, and to fœtal causes in 13, or 18 per cent., with the same ratio of mortality. The versions in head presentations, 47 in number, comprised 24 for inertia, 6 for contracted pelves, 1 for rigidity, 1 for recto-vaginal cyst, 8 for hæmorrhage, 5 for prolapsed cord, 1 for prolapse of hand, and 1 for parietal position; 40, or 85 per cent., maternal causes, with 1 in 2·5 children dead or dying, and 7, or 15 per cent., fœtal causes, with a death-rate of 1 in 3·5. Of the cases due to inertia, convulsions, and hæmorrhage a considerable proportion would doubtless be averted by hygienic precautions, especially during pregnancy, but in the majority of instances, and particularly in hospital practice, the physician has little or no opportunity to enforce these precautions, and among the poorer classes too often the conditions of health are unattainable.

The face presentations in Lachapelle's catalogue were 100 in number, or 1 in 222·4. Of these, 88 were spontaneously born; 9, or 1 in 9·7, dead or dying. Of the 5 forceps deliveries and 7 versions, all were for inertia except 1, in which a brow presentation was rectified by forceps, the mortality being 1 in 1·7. Thus, in all the face presentations, we find a mortality of 1 in 6·25, or 16 per cent. Lusk computes the ratio of these presentations as 1 in 255·5, and quotes Winckel's statement that the mortality of children is 13 per cent. Swayne estimates the frequency as 1 in 231. The experience of Collins shows a mortality of 12 per cent. Most of these records, however, concern only the children born dead, omitting those which die soon after birth, so that the estimate based on Lachapelle's table is probably nearest to the actual death ratio.

Pelvic presentations (including breech, foot, and knee) are stated by Lachapelle as 1 in 27 labors; by Swayne and Tanner as 1 in 38, the breech presenting about twice as often as the feet or knees. The mortality, according to Lachapelle, is a little over 25·5 per cent.; to Tanner, 33 per cent.; to Meigs, over 20 per cent.; to Collins, 37 per cent.

Shoulder presentations are, by the estimates of different observers, as follows: Lachapelle, 1 in 188·4; Churchill, 1 in 252; Spiegelberg, 1 in 180; Depaul, Dubois, and Pinard (quoted by Lusk), 1 in 117; Swayne and Tanner, 1 in 231; the infant mortality being about 50 per cent.

The comparative frequency of brow presentations is not easily estimated, since many of them are spontaneously converted into face or vertex before a diagnosis is made. As regards the mortality of children in recognized cases, Lusk cites 34 deliveries: 10 spontaneous (brow continuing), with 3 deaths during labor; 10 converted to face or vertex naturally, with 1 death; 9 extracted by forceps, brow first, with 1 death (from prolapsed funis); 5 changed by forceps to face or vertex, with no deaths—a total mortality of 4 attributable to the presentation, or about 12 per cent.

Taking the averages of all the data which I have been able to obtain, the probable frequency and child mortality (excluding non-viable fœtuses) of different presentations in a million births may be thus approximately stated:

PRESENTATION.	Total.	Dead or dying.
Vertex	960,000	53,500
Face	4,000	640
Pelvic	30,000	9,000
Shoulder	5,000	2,500
Undetermined, including forced delivery for maternal convulsions or hæmorrhage, embryotomies, contracted pelves, etc.	1,000	360
Total	1,000,000	66,000 = 6·6%, or 1 in 15.

In addition to these, there will be about 5,800 non-viable children, raising the death list to 71,800=1 in 13·9.

In the course of these million labors we shall meet with about 600 cases of placenta prævia, 4,000 of prolapse of the cord, 1,000 of contracted pelvis, and 2,000 of maternal convulsions (including those which occur before or after delivery as well as those during labor), with a maternal mortality of 1,400. Artificial delivery by forceps or version will be necessary in somewhat over 12,000 cases, with nearly 5,500 infant deaths. Of these instances of dystocia, about 48·5 per cent. will arise from maternal causes, and about 51·5 per cent. from fœtal causes. In the former category uterine inertia plays the largest part.

To what extent this loss of infant life may be reduced is a mere matter of surmise, but in its reduction obstetric science and hygiene must work together. The correction or better management of malpresentations is already showing beneficent effects in the practice of experts, and will doubtless ere long improve the general results; but even here there is room for great advance. The mortality from either natural or artificially induced pelvic presentations is, in the majority of examples, owing to compression of the cord, and this mortality is so large as to cast a shadow of doubt upon the propriety of podalic version in many cases in which it is advocated by some eminent authorities. According to Churchill, version in normal pelves is fatal to more than one third of the children, and in contracted pelves the death-rate is, of course, much larger. Lusk, who is wisely conservative in this respect, argues that, with a conjugate diameter of more than three inches and a half, nature is, as a rule, adequate to accomplish delivery. In the statistics cited by him, version in ordinary flattened pelves was followed by the death of 50 per cent. of the children; version in generally contracted pelves by about 90 per cent. of fœtal deaths; with the use of forceps above the brim, nearly 40 per cent. of mothers and over 60 per cent. of children died; while in spontaneous deliveries less than 3 per cent. of mothers and 13 per cent. of children were lost. Inasmuch as a large proportion of deformed pelves arises from rickets in early life, and a smaller from malacosteon in later years—both being principally results of insanitary conditions—it is not only possible, but probable, that, as the knowledge and application of hygiene become more diffused, these causes of dystocia will be vastly diminished in number; indeed, their frequency is demonstrably in inverse ratio to the prosperity of a community. So, also, watchfulness and prophylactic treatment during pregnancy may (and in the best practice do) decrease enormously the percentage of puerperal convulsions.

Premature or abortive births, as they arise from general ill health or local disease of the mother (including many cases of placental degeneration), or, occasionally, from chronic lead poisoning, may to a certain extent be preventable by hygienic or gynæcological means; those from external violence or nervous shocks will continue to hold their place on our records as long as feminine impulsiveness, staircases, and brutal husbands exist, and autocratic drivers usurp their reckless right of way.

As regards the effects of dystocia on the later life of the child, little can be learned. In patients whom we see as adolescents or adults we can rarely ascertain the character of the birth or the condition of infancy. None of us can doubt, however, that the morbility from this source is very great. From the French returns Farr calculates that out of a million children born, 29,121 die in the first week, 22,128 in the second week, and 22,236 in the next sixteen days, making a total of 73,485 in the first month. The English Life Table computes a somewhat less mortality—*i. e.*, 46,500 deaths in the first month, 17,200 in the second, 12,180 in the third, 10,100 in the fourth, 9,550 in the fifth, 9,030 in the sixth, 8,550 in the seventh, 8,080 in the eighth, 7,660 in the ninth, 7,250 in the tenth, 6,870 in the eleventh, and 6,520 in the twelfth, a total of 149,490 to the million in the first year. Many of these early deaths are produced by insanitary conditions, as is proved by the difference between the "healthy districts" of England and Liverpool, in the former of which 36,610 per million children die within the first month, while in the latter the mortality during the same period is (or was when Farr's analysis was made) 54,490 to the million. It is to be regretted that the registration of vital statistics is so imperfect in this country as to preclude any attempt to classify by months the mortality under one year; but the data, such as they are, indicate that, in the United States generally, about 25 per cent. of live-born children die during the first twelvemonth.

It would not be unreasonable, perhaps, to assume that at least half of the deaths under one month are attributable to accidents in parturition, and that a large residuum of those occurring in the first year has a similar origin; but the admirable reports of Farr may enable us to go a step farther in the field of inference. The death-rate under one year per 10,000 births in England, for the three years ending with 1875, was 1,527. Of these, 95 were ascribed to the acute zymoses. 29 to "teething," 171 to diarrhœa, 263 to "lung diseases," 98 to tuberculosis, 128 to prematurity, 267 to "atrophy," 14 to "suffocation," and 251 to convulsions, leaving 211 "not stated." The deaths from prematurity, "atrophy," and convulsions constitute nearly half of the mortality, all of the former and a considerable proportion of the latter two being referable to the time or act of parturition, and some of the pulmonary disorders having their predisposition, if not their origin, in atelectasis at birth. In Farr's *March of an English Generation*, based on the labor of over thirty years, he computes that the average deaths per million under one year will be 149,493, of which 30,637 will be from diseases of the nervous system and 21,995 from respiratory maladies. West, taking a wider view of "nervous" disorders, ascribes to these 30·5 per cent. of all the deaths under one year, and to convulsions alone 73·3 per cent. of the "nervous-system" mortality—equivalent to 33,421 to the million births.

After the earlier weeks of this perilous first year, convulsions, like "atrophy," are often due to maternal neglect or improper management (most notably in the administration of the various atrocious infant foods which flood the market and fill our waste-baskets with their "sample packages"), and sometimes are reported as causes of death when they are really but forerunners of rapidly fatal febrile disorders. But in an unascertainable proportion of cases they are unquestionably the result of compression of the head during delivery, and in such instances, according to West, tend to recur without obvious exciting cause, and to retard or retrograde mental development, leading very often to later epilepsy. Beau (quoted in Reynolds's *System*) found, out of 211 epileptics, 17 (8 per cent.) congenital, and Hughlings Jackson observes that "epileptic fits in adults not rarely date from convulsions in infancy." Nothnagel assigns to overlapping of the cranial bones during forceps extractions or tedious and difficult labors the causation of meningeal hæmorrhage—usually extravasation into the meshes of the pia—from which the children in the majority of instances are either born dead, or linger for a short time, or, rarely, recover to swell the morbidity of succeeding years. Erb refers to the occurrence of spinal meningeal hæmorrhage from difficult or instrumental labor. The principal injuries to the child in dystocia or instrumental interference are: depression or fracture of cranial bones, with or without laceration of brain; "apoplexy of nervous centers"; too tight hold of the forceps, leading occasionally to hemiplegia; and ruptures of viscera.

These considerations emphasize the importance of sound judgment to decide between the dangers of compression of the head by the maternal genital passage or by the forceps, and to determine when to apply the latter to the best advantage. It is undeniable that many lives which would have been sacrificed in the days of traditional prejudice against artificial aid are now saved; but there is reason to fear, with Playfair, that "the pendulum may have swung too far in the opposite direction." Not alone in simply tedious labors without indication of incompetence of the natural powers, but frequently to accelerate normal parturition, for the mother's comfort, or for economy of the accoucheur's time, forceps are used with as little regard for the welfare of the infant as the average street-car conductor has for the expectant passenger, or the "protectionist" legislator for the interests of the unprotected consumer, and, in inexpert hands, with a plentiful crop of maternal lacerations for the lucrative reaping of gynæcologists. Lawson Tait's disputed statement—that the infant mortality from forceps delivery in impacted labor is 1 in 7 or 8—is corroborated by Dr. J. G. Swayne (*Brit. Med. Journal*, April 26, 1890), who reports 211 instrumental extractions in difficult and protracted labors, "without reckoning complications," and 30 fœtal deaths, or 1 in 7; pointing out a hitherto unnoticed source of danger in the accidental pressure of the cord against the child's neck or head by the blade of the forceps.

Excessive mortality—implying a still greater morbidity

—continues through the first five years, the deaths during this period, in England, being 263,182 to the million births. In this State, by the only method of calculation possible, they constitute 37 per cent. of the total deaths at all ages. Deducting the first year's fatality, the subsequent four years produce 113,689 deaths, of which 9,428 are from diseases of the brain and 23.950 from respiratory diseases and phthisis. In Massachusetts the registration reports, as cited by Dr. T. B. Curtis (Buck's *Hygiene*), attribute from 10 per cent. to 15 per cent. of all deaths under five to "tuberculosis and scrofula." More than half of the death and sickness of this first lustrum arises from insanitary environment, as is evident from a comparison of the statistics in healthy and unhealthy districts, and is therefore amenable only to general hygiene, and about one third from zymotic disorders; but of the remainder an important reduction may be hoped for in the progress of obstetric science and art. After the age of five years, official statistics afford no ground for even guessing the effects of dystocia or premature births upon mortality and morbility; but the experience of most observant physicians will support the conclusion that they are by no means insignificant.

Turning now to the maternal aspect of the question, and relying, as before, mainly upon Farr's English statistics, we find that of the 488,255 girls born in the hypothetical million whence his "generation" takes its start, 342,281 pass the age of fifteen. Of these, 79 per cent., or 270,402, marry. According to the inquiries of Sir James Simpson and others, about 10 per cent. of marriages are sterile; so that 243,362 of these wives bear children at the rate of 5·23 each, and 6,921 perish in consequence of the process, or 1 in 35 mothers in all their childbearings (2·8 per cent.), which is equivalent to 1 maternal death in every 183 parturitions. These figures apply to all classes of the population, and, of course, overstate the mortality where skilled assistance is at hand. Thus the maternal mortality from childbirth is variously estimated by obstetricians as from 1 in 200 to 1 in 212, while Dr. Rigden (quoted by Farr) in 4,132 private cases had a death-rate of less than 1 in 516. In the records of hospitals and of the experience of consulting obstetricians, more difficult cases, and consequently a higher rate of fatality, are likely to occur. From our prophylactic point of view, it is desirable to discriminate the deaths directly due to the act of parturition from those caused by secondary puerperal diseases, and this has been done by Farr in his separate classification of "metria" and "other accidents of childbirth." We have further to consider the influence of age during the fertile period of woman's life, which, in temperate latitudes, may be regarded as extending from fifteen to a maximum of fifty-five. The following table shows the ratio of deaths of mothers to the number of children born:

Age.	Metria.	Accidents of birth.	Total.
15–25	0·277%, or 1 in 361·7	0·391%, or 1 in 255·75	0·668%, or 1 in 149·7
25–35	0·148% " 1 " 675·7	0·277% " 1 " 361·7	0·425% " 1 " 235·3
35–45	0·154% " 1 " 649·3	0·479% " 1 " 207·9	0·633% " 1 " 157·9
45–55	0·163% " 1 " 613·5	0·720% " 1 " 138·9	0·883% " 1 " 113·2
15–55	0·172%, or 1 in 581·4	0·358%, or 1 in 279·3	0·530%, or 1 in 188·7

In the State of New York about 1 per cent. of the total mortality from all causes is returned as "puerperal," but this includes other accidents of parturition also.

Nearly the whole of the mortality under the head of metria ought to be avoidable by aseptic midwifery and after-management, vastly diminishing the perils of the lying-in chamber, especially to primiparæ, and obstetric skill may lessen that from other accidents of childbirth. We hear less now than thirty years ago of metritis or sloughing from too prolonged pressure, of rupture of the uterus, of fatal exhaustion or post-partum hæmorrhage; but, even with our better modern training, a great part of such preventable lethality will remain beyond our control as long as ignorant and uncleanly midwives conduct the majority of labors among the poorer classes; for, particularly in rural districts, nearly half of all confinements take place without the attendance of a physician. The enormous amount of morbility entailed upon women who escape death is familiar to every one who has seen much of gynæcic practice. Moreover, it is among the overworked and often underfed poor that malpresentations and pelvic deformities are most prevalent and obstetric skill most needed. To demonstrate how much such skill may accomplish, Dr. J. T. Hartill (*Brit. Med. Journal*, September 27, 1890) has recently reported the results of 2,000 consecutive confinements, largely among the wretched operatives in the "Black Country," comprising 14 cases of complete or partial placenta prævia, 61 pelvic presentations, 24 transverse, 60 contracted pelves, 29 cases of uterine inertia, 12 of rigidity of soft parts, and 1 of ovarian tumor; 164 applications of the forceps (1 in 12 of all labors); yet, despite these adverse circumstances, there were but 8 maternal deaths from childbirth, or 1 in 250 mothers, 2 from subsequent metritis, 1 from embolism, 1 from phthisis, and 1 from pneumonia—a total mortality, assignable to labor, of 11, or 1 in 182.

The term "aseptic midwifery" has been advisedly used, because in obstetrics, as in surgery, our duty should be to preserve from infection rather than to wait to combat it after it has occurred; and this is usually practicable in the domiciles of the well-to-do. Amid unwholesome surroundings, "antiseptic" measures may be prudently adopted; but these need hardly extend to a bichloride baptism of the child's advancing head or to its birth into a carbolized fog, and enough cases of obstetric poisoning by corrosive sublimate have already been recorded to render us cautious in the employment of strong solutions of so dangerous an agent.

Imprudence or mismanagement after parturition is a fertile source of local disease or general ill-health, reacting, almost of necessity, upon subsequent offspring, and so, to a certain extent, upon the biological condition of the race.

Nothing has been said of the graver ventures of modern obstetric surgery, such as Saenger's modification of the Cæsarean section, Porro's or Thomas's operations, or the surgical treatment of extra-uterine pregnancy, for the reason that these are still *sub judice* among those to whom we must look for an authoritative opinion, and the cases requiring

them are happily too few to warrant statistical deductions. The object I have had in view has been to present sufficient data whereon to base a conjecture, if nothing more, of the saving of life and health which may yet be effected by obstetric medicine.

As regards social conditions, I have little to say beyond expressing the belief that misery rather than midwifery is responsible for most of the degradation which blots our vaunted civilization. It may be that in some cases such misery is the outcome of physical disability dating from birth or parturition, but in more instances it is the result of acquired vicious habits. Social statistics show that the numbers of murders, suicides, and other kinds of crime bear about the same proportion to population every year; but of the ætiology of criminality nothing can be positively affirmed. Even those who dogmatically ascribe all the ill-doings of the world to alcohol have still to find some antecedent factor, and to explain why the vast majority of consumers of alcoholic beverages refrain from crime. Inebriety is often the excitant, but the predisposition must be sought behind it. "*In vino veritas*" has a wider philosophical meaning than they who quote it ordinarily wot of.

Recent anthropometric examinations of convicts have frequently detected cranial malformation or asymmetry; it is not yet proved, however, that this is more common in criminals than in the law-abiding classes, and, if it were, the wildest flight of fancy would fail to reach a guess of its possible connection with dystocia. If it be considered that civilized life is artificial, and that the absolutely natural man would be, in the eyes of the civilized man, an habitual criminal—gratifying all his animal propensities; taking, furtively or forcibly, whatsoever he coveted; killing his brother savage when prompted by any grievance; stealthy or violent in accordance to the degree of his strength and courage—then the "reversions to a lower type" which police records depict may be better understood, and imputed, after the hereditary transmission of an imbruted organization, to neglected childhood, lack of moral training, and evil communications.

The vexed question of heredity (not so much of disease as of proclivity to disease) has little relation to obstetrics, save as it has led some enthusiasts to imagine an impossible prophylaxis by forbidding the marriage of physically, mentally, or morally unhealthy persons, and in this way diminishing obstetric practice, except in illegitimate births; and it is doubtful if anything but a destructively retrogressive midwifery or an increasing prevalence of oophorectomy can materially reduce hereditary morbidity, since delicate, and especially consumptive, women seem to be more apt to conceive and less likely to miscarry than their more robust sisters. As a "glittering generality" it may be asserted that every obstetric advance which saves mothers from invalidism and children from incapacity for future effort must promote the social condition of the race; but politico-economic rules and the inexorable operation of natural laws will probably always overshadow in this respect the influence of medical science, or even of congressional legislation.

CHRONIC DISTURBANCES IN JOINTS.*

By FRANK HARTLEY, M. D.

My object in presenting a paper upon this subject is simply to give expression to the fact that I consider the proper diagnosis of chronic joint disturbances is the *only* means of deciding the treatment. We have now *so many* methods of treatment recommended for these disturbances, so many attestations to the superiority of the one over the other, that, when we come in contact with a chronic disturbance in a joint, we are completely bewildered in a choice. For some it is quite sufficient that the disturbance is chronic alone. The ætiology, the condition within the joint, and the natural course of the disease are completely overlooked. They treat rheumatoid arthritis, arthritis deformans, arthritis nodosa, and even neuropathic joints, with antirrheumatic and antisyphilitic remedies, apply splints and counter-irritation to papillary and cartilaginous synovitis, look upon syphilitic arthritis in children as tubercular, and subject osteomyelitic arthritis to a long course of antirrheumatic treatment. Out of this medley of opinion as to treatment the best course is a correct diagnosis, for, if we lay aside the various remedial agents and begin at the other end, establish correctly the diagnosis, the ætiology, the condition within the joint, and the natural course of the disease, the means of cure, where such exists, become very few in number. I refer particularly to those varieties known under the head of chronic rheumatic arthritis, arthritis deformans and nodosa, the malum senile, the neuropathic, syphilitic, and metastatic arthritides.

An exact knowledge upon many of these varieties is wanting, so that we are forced to classify them, anatomically and according to their lesions, as they exist in the articular ends of the bones, the cartilages, the synovialis, the ligaments, and the parasynovial tissue. The bones and the synovial membrane are important not only as the place of origin, but, with the cartilage, ligaments, and parasynovial tissue, as giving us the local manifestations of the lesions.

The synovial membrane, the intima of which is rich in cells, possessed of a well-marked vascularity, and surrounding a cavity filled with fluid favorable to the generalization of any focus, responds quickly to disturbances of nutrition and inflammatory irritants.

In chronic disturbances of nutrition and inflammatory processes the changes observed are its increased vascularity, its thickness, and its greater density. The normal folds and tufts which exist in childhood and old age, at the reflection of the synovial membrane upon the bones near the cartilage, inclose within them a rich network of blood-vessels or fat, or consist of a comparatively non-vascular fibrillary tissue, with or without inclosed cartilage cells. In chronic pathological processes these become enlarged and vascular, and, according to the predominating changes, give us the variety of synovitis.

In the chronic serous synovitis (the hydrops articulorum chronicus) these simple changes are present, with a large amount of serous fluid, with or without fibrinous floc-

* Read before the New York Clinical Society, September 26, 1890.

culi (or a fluid colloid in character), distending the capsule to such an extent in some cases as to produce herniæ of the synovial membrane.

In many cases of syphilis, and especially in arthritis deformans, newly developed and dendritic tufts and villi cover the entire surface of the synovialis, forming irregular and dense sessile or pedunculated outgrowths.

As these papillary growths may consist of a vascular network, fat or cartilage, the varieties of synovitis have been named synovitis chronica serosa, papillaris, prolifera, simplex, cartilaginea, and lipomatosa (lipoma arborescens articulationis). Moreover, in some cases a new factor is added in that fibrin is deposited upon the synovial membrane itself, its papillæ or tufts, producing in this manner a number of thick, rounded, or irregularly-shaped nodules, sessile or pedunculated.

Composed thus of fibrin and the contents of the tufts and papillæ, or of fibrin alone, these, when loosened or floating within the joint, give rise to the varieties of corpora oryzoidea. Such a condition is seen in the chronic serous and tubercular synovitis, and, together with other varieties of corpora aliena, exist in arthritis deformans and neurogenic arthritis. In the so-called chronic rheumatic arthritis the synovialis presents, besides its vascularity, a new connective-tissue growth with cicatrization. This process, synovitis cicatricans, exists not only in this variety (best seen in the arthritis rheumatica chronica ankylopoietica), but also in all suppurative processes, especially in catarrhal and gonorrhœal synovitis. In the so-called secondary period of syphilis we have to do with a simple serous synovitis; but in the tertiary and hereditary syphilis—though, so far as the synovialis is concerned, we find about the same changes—the prevailing and characteristic marks are the papillary growths and the gummata in the subsynovial fatty tissue at the reflection of the synovialis, in the fibrous capsule, the bones, and the neighboring bursæ.

The importance of the cartilage as a starting-point for inflammatory changes within a joint is not of moment. It is non-vascular, it receives its nutrition by plasmatic circulation, and is dependent upon its neighboring structures for the changes which may occur within it.

Yet we recognize such conditions as chondritis pannosa granulosa (cribrosa) and hyperplastica, but consider them only as depending upon similar conditions in synovialis or bones.

In the simple chronic joint inflammations (disturbances of nutrition) the cartilages are not generally involved other than that they are more opaque than usual. In the chronic non-suppurative processes the cartilages are at the most superficially fibrous from an extension of similar processes in the synovialis; whereas in the suppurative and tubercular involvements, granulation tissue from the bones and the synovialis extends over and into the cartilage. In the acquired syphilis in the tertiary stage and in the syphilis of children, defects in the cartilage occur, resulting in the loss of a portion of it and its replacement by a radiating connective-tissue scar from gummata in deeper portions of the articular ends of the bones, or in the cartilage adjacent to the bone.

In the arthritis rheumatica chronica ankylopoietica the cartilage is superficially fibrous and vascular from the vessels within the synovialis and spongiosa of the bones. As this process advances, a gradual transformation of the cartilage into connective tissue takes place, and opposing surfaces become united. As this connective-tissue transformation of the cartilage does not involve the whole surface of the cartilage at once, spaces covered with an uninvolved cartilage remain between these connective-tissue areas, and the original joint cavity becomes subdivided into a number of smaller cavities filled with fluid. In the senile arthritis the cartilages are likewise fibrous, but upon pressure points an "Usur" occurs, which subsequently leaves the bone bare (the articular lamella), polished, and eburnated. In the arthritis deformans, on the contrary, marked changes take place in the cartilage. Superficially it is fibrous and fissured, but in the deeper portions—*i. e.*, near the bone—circumscribed foci of softening are present. These changes result in the formation of a cancellous tissue, which toward the center of the cartilage undergoes a further process of absorption, with a gradual disappearance of the cancellous lamellæ and a partial destruction of this osteoid tissue, which has here replaced the cartilage in its lower layers. Superficially the cartilage remains fibrous, sclerosed, and fissured. On the periphery of the cartilage, on the contrary, tuberous outgrowths (stalactites) occur, consisting of bone and cartilage, and so raising the articular cartilage that the former level is altered. This latter process, together with the central foci of softening, leads to a complete transformation of the joint in which irregular and tuberous outgrowths, bony and cartilaginous, occur upon the borders of the cartilages, while centrally it is hollowed out, grooved, and eburnated. In the severer neuropathic arthritis the shape of the joint is likewise altered in a remarkable manner. The cartilage is, however, simply dissolved, leaving the bony extremities bare.

In consequence of the use, the bone becomes smooth and deeply grooved, and, owing to its brittleness, subject to continual fracture and repeated hæmorrhages. In this manner is explained the variety of foreign bodies found in such joints, the bony, the cartilaginous, and fibrinous coagula. They are due in part to the multiple fractures, in part to the cartilaginous and papillary synovitis.

In the metastatic and severe purulent synovitis, foci are found in the spongiosa of the articular ends of the bones; whereas in the non-tubercular chronic inflammations, the senile, the neuropathic, and the arthritis chronica rheumatica ankylopoietica; the bones are atrophied, softened, and give evidences of retrogressive metamorphosis. In the arthritis deformans, besides the gradual transformation of the deeper portions of the cartilage into an osteoid tissue and a sclerosis of the superficial layers, there is an osteitis rareficans of the articular extremity in which the salts of lime being wanting, renders the bone softer than usual, so that, on pressure point, grooves and fissures are found; and where no pressure is exerted, tuberous outgrowths in various stages of calcification may be seen. In the syphilitic joint inflammations the bones are the seat of a syphilitic caries (syphilitic osteomyelitis) or of gummata, and in

many cases of hereditary syphilis of a syphilitic osteochondritis and periostitis.

These gummata are most frequently situated, however, upon the peripheral portion of the ends of the bones, and are rarely within the spongiosa; whereas in tuberculosis the process begins near the epiphyseal line in the form of a grayish-red or whitish mass of tubercles or granulation tissue, or in the form of a more diffuse tubercular infiltration of the spongiosa. The bones in syphilis are not *greatly* changed in form, yet there is always some hyperostosis.

The changes occurring in the fibrous capsule and ligaments are seen principally in relaxation or contraction.

They are contracted in chronic polyarticular rheumatism (art. chronica rheum. ankylopoietica), malum senile, and in the continued fixation of chronically inflamed or even normal joints. They are relaxed in arthritis deformans, neurogenic and rhachitic joints. All other changes occurring within these structures are similar to those occurring within the joint.

In a diagnosis of the variety of joint disease we are to examine carefully the condition of the synovial membrane and bones principally, as well as the cartilage, ligaments, and parasynovial tissue. Unless such a careful and accurate local examination is made, we are prone to mingle one form of chronic inflammation with another and to neglect to make use of one of the most important means toward an accurate diagnosis. So similar are the changes in the synovialis that, unless careful attention is given to the rest of the joint, the anatomical part of the diagnosis is overlooked and an attempt is made to decide the case upon subjective symptoms alone. This very thing is too often performed in a perfunctory manner, without an exact knowledge of characteristics of the diseases liable to cause a disease within a joint. We should not, however, be content to decide any case upon what we can find in the joint alone. As far as possible, the ætiological factor should be sought for; whether this irritant (chemical or micro-organic) arrived within the joint from a wound, from the neighboring tissues, or from foci at a distance.

In suppurative processes—osteomyelitis, tuberculosis, and syphilis—the joint invasion takes place from the neighboring tissues by a process similar to the original focus, either by means of the lymphatics directly causing an acute or chronic inflammation, or the focus itself advances and ruptures, causing generally an acute invasion.

More frequently, however, the irritant involves the joint by means of the blood-vessels.

This is the case in acute rheumatism, gout, syphilis, tuberculosis, and metastatic inflammations, the result of the infectious diseases. Possibly this is the case in polyarticular arthritis deformans and many chronic and rheumatic arthrites.

Moreover, the irritant may exist in the blood only occasionally, and then involve the joint. Such is probably the case in tuberculosis, metastatic (gonorrhœal) synovitis, and some chronic rheumatic synovitides.

In just these cases the focus is to be found in the suppurative processes in the skin, the subcutaneous tissue, the bones, and mucous membranes, especially in the tonsils, pharynx, and nose, in the lungs, the intestines, and the genital and urinary organs.

Such a method of infection is thought to be common and is to be considered in every case. It is more than probable that this is the case when we consider how the anatomical structure of the spongiosa favors the slowing of the current of blood and accumulation of an inflammatory irritant within the ends of the bones as well as the anatomy of the synovialis and the relation to the joint cavity of its lymphatics. When a joint is alone involved, either the process is a simple disturbance of nutrition without infection, or the infection takes place from distant parts by means of slight injuries to the spongiosa or the synovialis, in which either an extravasation of blood or a thrombus in the vessels admits the infection and produces an inflammation of greater or less severity, depending upon the amount and intensity of the agent.

In this manner new diseases may be added to old ones. Such may be the case in the tubercular involvement of previous simple synovitis, metastatic and so-called rheumatic arthritis, as well as in the arthritis deformans the outgrowth of simple or rheumatic synovitis. How heat and cold act in producing disturbances of nutrition and inflammatory changes we do not know. It is probable, however, that they cause disturbances in the walls of the vessels, in the circulation of the blood, or in the cellular elements in the tissues, favoring the collection or escape of the irritant not only in the neighborhood of the joint, but also in the joint itself.

Nor should our investigations be confined to these methods alone. We are to examine in all cases to see what diseased conditions of the nervous system are present to prepare a point of diminished resistance to disturbances of nutrition or possibly secondary infections. Wherever we find any similarity to neurogenic joints, we should institute a careful examination for the early stages of locomotor ataxia, syringomyelia, compression of the cord, etc.

As the subsequent course of any disease within a joint depends so much upon this condition, it is highly important to recognize it in its earliest stage, both for prognosis and for treatment.

It is only by understanding specifically the point of origin, the condition within the joint, and the ætiology, that we are able to act rationally in our prognosis or methods of treatment.

The first form which to me seems of importance is the chronic serous synovitis. Under the chronic serous synovitis we include a number of varieties depending upon the changes within the synovialis, yet all these varieties are characterized by the fact that they are local disturbances of nutrition occasioned by a trauma, and appearing at first either as an acute or chronic process.

Depending upon the predominating changes in the synovialis and the chronicity of the process, it appears as a hydrops articulorum chronicus (chronic serous synovitis), a synovitis papillaris, a synovitis prolifera simplex, synovitis cartilaginea, and synovitis lipomatosa (lipoma arborescens articulationis).

The symptoms likewise vary with the character of the

changes in the synovialis, whereas in the hydrops articulorum chronicus the characteristic is the large quantity of fluid, the herniæ of the synovialis, and the want of all restriction to motion within the joint; in the synovitis papillaris, cartilaginea, and lipomatosa these symptoms are not marked nor have they any diagnostic value. Though there may be a quantity of fluid within the joint, it is small in amount, except during exacerbations as the result of overuse or injury. The important changes are seen on the examination of the synovialis, and the symptoms diagnostic of any of these varieties are dependent upon this condition within the synovialis alone. We may thus have a joint disease which simulates in the exudation and in its sudden attack the synovitis of scurvy, morbus maculosus, and hæmophilia; in the quantity of fluid and in the character of the synovialis, a deforming or neurogenic arthritis, a syphilitic or tubercular hydrops. The presence of foreign bodies within the joint—blood, fibrin, fat, or cartilage—whether movable or free within the joint, or pedunculated, gives at times a variety of symptoms with which we are familiar under the term of foreign body within the knee joint.

The character of the fluid within the joint is one in which we find a few white blood cells, portions of tufts which have been separated from the synovialis, and red blood cells following manipulation or use of the limb. Fibrinous flakes of varying size and shape (rice bodies) are frequently seen, and exceptionally a fibrinous deposit is present to such an extent as to fill completely the cavity as a mold. The fluid is rarely under great pressure within the joint, nor are the ligaments stretched or loosened so that the joint becomes flaccid. The bones are never involved, although here and there upon the cartilage small eroded surfaces or spots of chondritis pannosa may be present. The joints most frequently involved are the knee, elbow, foot, and hand.

It is to be distinguished from the varieties of disease above mentioned in the first place; secondly, we are to determine as far as possible the changes in the synovialis, for upon these changes will depend our treatment and ability to cure with or without ankylosis. It is a variety most frequently mistaken for tubercular and syphilitic hydrops, for commencing arthritis deformans, and a foreign body in the joint.

A second variety of importance for diagnosis is the metastatic variety—a variety which, so far as my experience goes, is very frequently overlooked.

In the so-called infectious diseases arthrites are not uncommonly seen. In measles, scarlet fever, small-pox, cerebro-spinal meningitis (epidemic), pneumonia, typhus, dysentery, erysipelas, pertussis, epidemic parotitis, acute infectious osteomyelitis, puerperal fever, pyæmia, septicæmia, gonorrhœa, catheterismus, chronic cystitis, glanders, and malarial disease the joints may be involved as a serous, sero-purulent, or purulent arthritis. Rarely as a diphtheritic process with small hæmorrhages they occur in puerperal fever, acute infectious osteomyelitis, erysipelas, pyæmia, septicæmia, and glanders. In addition to these, in variola, cerebro-spinal meningitis, suppurative parotitis, and scarlet fever it is seen as a purulent arthritis. In other diseases and in milder infections in the above it appears as a serous or sero-purulent arthritis. These varieties depend upon degrees of infection or upon mixed infections. In the serous exudates the specific micro-organisms are frequent, but are always present with other varieties, whereas in the purulent they are scarcer or are not present at all. They are characterized by the fact that they are multi-articular and occur during the existence of the disease.

In measles, cerebro-spinal meningitis, pneumonia, parotitis, and puerperal fever they generally occur shortly after the beginning of the disease; in catheterismus, within a few hours; in scarlet fever, in the period of desquamation; in variola, in the period of suppuration; in diphtheria, gonorrhœa, and dysentery, toward the end of the disease.

In the period of convalescence these arthrites are generally monarticular and serous or sero-purulent.

When serous, they remain a few days and then recede quickly or require a longer time to disappear. They not uncommonly remain, however, as a chronic inflammation in one or more joints. In gonorrhœa this is especially the case. The arthritis continues for weeks with moderate pain, or resolves completely to return again with moderate pain and swelling. There is thus in time produced a thickening of the synovialis, the formation of enlarged tufts and villi, with a moderate amount of fluid in the joint, and a condition of so-called chronic relapsing hydrops. It is indeed the characteristic of these metastatic inflammations *to relapse*, and is an important factor in their diagnosis. Such synovitides I have seen in gonorrhœa, where the disease remained as a multi-articular synovitis.

A synovitis papillaris and cartilaginea in one knee, a chronic serous synovitis in the other knee, a synovitis cicatricans in one wrist and ankle, an acute exacerbation upon a chronic serous synovitis in the other ankle, existed in one patient.

It was the outgrowth of a gonorrhœa acquired three years previously and had been present since that time. Each exacerbation of his chronic gonorrhœa was generally attended with some joint complication.

In cases where the disease is catarrhal they lead to fibrous or bony ankylosis, or resolve completely. In the purulent form, however, though recovery may occur, death generally results.

Sometimes without operation they become chronic, existing as a purulent arthritis with necrosis of the articular extremities of the bones, or become secondarily tubercular. In the period of convalescence the joint most frequently involved is the hip, and the diseases in which this occurs are generally typhoid, scarlet fever, pneumonia, and acute infectious osteomyelitis. Spontaneous luxation is not uncommon, even where no suppuration was present. I have seen cases of this kind in typhoid fever, measles, and infectious osteomyelitis.

Even when such joints have not become tubercular they are often considered so because of their chronicity alone, and, no matter how treated, whether by operation or mechanically, are held up to us as examples of the advantages of one or the other methods of treatment in this disease, when the actual condition is entirely of another character.

Such errors in diagnosis I have not infrequently seen in the acute multiple epiphyseal osteomyelitis. These cases have been indefinitely treated as acute rheumatism in their first attack, and in their chronic form considered as rheumatism or tuberculosis. Hitherto we have paid attention mostly to the osteomyelitis of the shafts of bones, yet greater attention should be given to that of the epiphyses, which appears under the form of an arthritis (multi-articular or uni-articular), simulating in the early stage an acute multi-articular rheumatism and in the later stages varying according to the character of the arthritis—*i. e.*, the degree of the osteomyelitis and character of the synovialis (serous, catarrhal, or purulent). This disease is that variety of rheumatism, if I may so term it, in which antirrheumatic remedies have no effect and in which fistulæ, with or without necrosis or simple catarrhal or purulent arthritis, succeed the acute attack. How many of the good results in tuberculosis are due to this error in diagnosis I am unable to say. I do not think, however, from my experience in operations upon the joints where one is able to see clearly the lesion, that all of our diagnoses of tubercular joints are by any means correct. Our errors, I am sure, give more cures for tuberculosis than properly belong to it.

A third variety is that to which we give the name of chronic rheumatic arthritis, which includes several diseases differing in their cause and course, but having very similar anatomico-pathological changes. These consist in an infiltration and thickening of the capsule, which becomes cicatricial, while the bones and cartilages are only superficially destroyed without hypertrophic changes, and in which the tendency of the opposing surface is to unite. Yet these cases differ so much in their course that it is wrong to class them under one head.

According to many, they arise from acute rheumatism or exist as primary chronic inflammations, an uncertainty which seems to exist from the fact that marked rheumatism is not infrequently present where only slight fever exists with a gradual but steady involvement of the joint, or in which the disease begins as endocarditis, to which the joint complications are subsequently added.

Yet others look upon these joints as rheumatic only when preceded by a distinct and veritable acute rheumatism, with its relapses and complications.

I do not wish to speak of the easily recognized varieties of chronic rheumatism, either the infectious variety, arthritis rheumatica chronica ankylopoietica, or the chronic serous synovitis seen in the outgrowth of previous attacks of rheumatism, as their characteristics are marked by constant relapses, gradual and increasing ankylosis, paresis of the muscles about the joint, the subacute exacerbations with œdema and redness, and the multi-articular character without fever; or the rarer variety of monarticular chronic rheumatism.

Nor has it seemed to me that the malum senile, arthritis nodosa, or the multi-articular variety of arthritis deformans has offered any great chances for difficulty in diagnosis. As a monarticular disease, however, arthritis deformans certainly demands attention, and is not infrequently overlooked.

Its ætiological factor is not known.

Although injuries to the joint in man and the injection of weak inflammatory products into the joints of animals have produced somewhat similar conditions—though cases have been reported as following synovitis serosa and gonorrhoica—still, we are as much in doubt about this as a factor as we are of its trophoneurotic origin.

The course of the disease, however, and the objective symptoms give us sufficient data upon which to base a diagnosis.

Existing in the younger class of people, its course is much more rapid than the multi-articular variety in the older people. It not infrequently follows contusions, distortions, and intra-articular fractures, though it may occur spontaneously—*i. e.*, to all appearances. Commencing with moderate pain, crepitation, and stiffness in the joint, there are gradually added neuralgic pains in the limb of some severity. Acute exacerbations, with an increase of fluid within the joint, occur from time to time, persisting for two to five days and slowly receding.

Yet, in all this process there is no ankylosis, no fever, nor suppuration. In the examination of the joint, we find a thickening of the capsule, the formation of tufts within the joint in the forms of the fibroma papillare (Virchow), lipoma arborescens, or the cartilaginous plates. On the articular ends of the bones we find an osteitis deformans, the result of which is to produce a softening and gradual disappearance of the lower portion of the articular cartilage, with a sclerosis of its superficial layers as well as the grooves and fissures within the joint at the point of contact of the articular ends. On the borders of the cartilage the advance of the osteitis is not impeded, and irregular outgrowths occur, producing such changes in the articular cartilages, by elevating and disturbing their natural position, as to lead to subluxations or imperfections in their full and free use. This process begins beneath the periosteum and gradually extends toward the medulla. It is similar in its course to an osteitis rarificans—*i. e.*, in the formation of Howship's lacunæ and the Haversian spaces. As in all diseases of bone, there is, together with this process, a formation of new bone both in the medulla and beneath the periosteum. This newly formed bone remains without the salts of lime for a long time, is softer than usual, and yields readily to the pressure exerted upon it. The process runs its course with calcification and sclerosis, so that in older portions, instead of a soft and yielding structure, a firm and resisting deposit of new bone is formed.

The failure in the deposits of the salts of lime in the earlier stages gives us a means of explaining why such great deformities occur within so short a time (one year) in such joints as the hip, the knee, and the elbow.

As the disease runs its course in sclerosis and calcification, it justifies us in a resection, when this is necessary either from the deformity or the severe pain.

The process is practically a disease of the joint, yet the joint symptoms are only a secondary process to a disease in the articular ends of the bone—an osteitis deformans. The objective signs are sufficiently diagnostic, yet they are not given their full weight in the earlier stages of the disease.

It is a very important variety; it is easy of diagnosis in

the later stages, but in the earlier stages it offers many difficulties when contrasted with other diseases, as osteochondritis dissecans and traumatic arthritis.

A fourth variety, in which I think many errors in diagnosis are made, is the arthropathies occurring in syphilis. It is not so rarely seen that in the acquired disease such a process is treated for acute rheumatism, and in the hereditary form is considered and treated as a tubercular process.

I have seen just such cases, where the treatment was carried so far as resection, or in which an antisyphilitic treatment was required to cure a persistent rheumatism.

In this disease we should consider the arthropathies both in the acquired and hereditary forms.

In the secondary period we have to do mostly with a subacute or chronic serous exudation within several joints. They are similar to metastatic arthritis, with which they may be classed. Existing as a multi-articular or uni-articular process with some fever, pain, and swelling, with or without a serous exudation within the joints, especially if the onset is sudden and an eruption is not marked, or not observed, or inquired into, it is apt to be looked upon as rheumatic, and so treated. More frequent than this variety, however, is that occurring in the tertiary stage. It is commonly uni-articular, subacute, or chronic in character, and is attended with a moderate exudation within the joint. The capsule is slightly thickened, with well-marked, papilliform, thick tufts upon the synovialis. The changes in the cartilage are peculiar, and consist of a transformation of the cartilage over circumscribed areas into a dense cicatricial tissue, somewhat depressed beneath the level of the surrounding cartilage and covered and bordered by small tufts. No new cartilage is here produced. It is simply replaced by a dense connective tissue due to subchondral gummata.

These cartilage defects and a papillary synovitis are peculiar to the disease and occur without, but generally with, a gumma in the bursæ, ligaments, or beneath the periosteum near the epiphysis, or as an accompaniment of a syphilitic osteomyelitis of the diaphysis which has advanced toward the epiphysis. The general result of such a process is a simple hydrops, yet suppuration may occur either as the result of an accidental infection or from the gradual or rapid breaking down of a gumma which has already involved the joint. As a sero-purulent or catarrhal exudation it follows subchondral gummata, whereas in the gummata in the bones, ligaments, or bursæ, fistulæ are slowly formed, and the suppuration is then added.

More interesting and difficult of diagnosis, however, are those cases of this disease seen in childhood and youth, the result of "syphilis héréditaire tardive." Here we are to observe particularly those symptoms which are characteristic in a general way.

The peculiar multiplicity and symmetry seen in these arthritides, the age (three to twenty-eight, five to fifteen), the bones involved—tibia, ulna, radius, humerus, and femur—their point of involvement, mostly the diaphysis, not infrequently the epiphysis, subacute or chronic osteo-periostitis ending in hyperostosis, "douleurs ostéocopes," and the syphilitic habitus—are all symptoms which should, in any case, lead us to suspect strongly the character of the lesion. A form most difficult of diagnosis is that in which there exists within a joint or joints a subacute serous inflammation, with moderate exudation, some swelling of the capsule, pain and redness in the skin, but without any observable changes in the bone. There are present within these joints changes in the cartilage characteristic of syphilis, foci of necrosis, or sharply bordered defects, while the synovialis presents only an inflammatory injection. The epiphyseal cartilage is in no way involved.

This variety I have seen in only one instance. The diagnosis must be made by exclusion, by the multiplicity and symmetry, the subacute course, and the joints involved. In this particular instance the child, three years old, was cured in about two months with antisyphilitic treatment, and in two years returned with other manifestations of hereditary syphilis.

More common and much easier of diagnosis are those cases occurring as a complication of a gumma in the soft parts about the joint or axis, seen in a periostitis and osteomyelitis of a neighboring long bone. Here the presence of the gumma or the osteomyelitis and periostitis, with thickening of the capsule and the papillary growth in the synovialis, makes the diagnosis comparatively easy. Such cases have been frequently seen during the last three years at the Roosevelt Hospital. A third variety in hereditary syphilis, and one which I think is not so *very* uncommon, is that in which an arthritis follows an epiphyseal periostitis and perichondritis by simple extension. They appear with a relatively rapid swelling of the epiphyseal periosteum, with a gradual serous exudation into the joint. As the process advances, the capsule is thickened and papillary growths upon the synovialis are added. This process may be attended with a puriform exudation into the joint, when such a focus breaks into the joint, or a complete separation of the epiphysis may take place. A relatively rapid circumferential swelling of the epiphysis, attended with an exudation within the joint, are the characteristic signs. The condition produced is somewhat similar to rhachitis, but differs from it in its rapidity and joint complication.

The joints most frequently involved in these varieties are the knee, the elbow, the metatarsal, metacarpal, and digital joints. These varieties are of great importance in diagnosis, and their treatment is so evident and brilliant that to make a mistake seems almost reprehensible. We will all of us make such mistakes, but we should attempt at least in all cases, especially in children, where the differential diagnosis between syphilis and tuberculosis may be somewhat uncertain, to give the child the benefit of a syphilitic course of treatment if any well-founded suspicions as to the character of the process exist. It is only in the suppurating syphilitic processes that any operative measures are necessary. Even here it is to be made subordinate to internal or local antisyphilitic remedies.

If I might be allowed to so express myself, Mr. President, I should say that, though not frequent, some of my best results in suspected tubercular joints in children have been cured in this way. I have seen, in all, four cases of this disease subjected to operative treatment. Two of them

were gummatous arthritis of the elbow; resection, return in both, cured by internal treatment alone. The other two cases had other joints involved. In one, a knee-joint, gummatous arthritis from subperiosteal gumma; resection return; cured by internal medication. The other case was one of irrigation and drainage of the knee. Return, cured by internal medication.

It should be our duty to recognize this variety of joint disease when it is present. In this variety, more than in any other, can a good functional result be obtained by internal local medication.

There is still another class of cases in which the chances of error in diagnosis are great. I refer particularly to the neurogenic arthritis occurring during the course of locomotor ataxia, compression of the cord, traumatic lateral spinal paralysis, acute myelitis, multiple sclerosis, syringomyelia, and injury to peripheral nerves.

It is not our province here to discuss whether the trophic centers are involved, whether nutritive anomalies in the bones exist, rendering them more fragile, or whether the bones maintain their normal density and compactness. There can be no doubt about the fact that neuropathic individuals are subject to all possible forms of arthritis as every one is. Yet the course of their arthrites are so modified by the disturbance in innervation that it is of practical value to consider them as a separate variety.

The analgesia and the increased vulnerability of the tissues in neuropathic individuals prepare a course distinctive for this class of cases. It is not necessary that an abnormal fragility of the ends of the bones be considered as a prerequisite condition. All that one requires is an intra-articular fracture and a continued use of the joint to develop a condition similar, but not so rapid as when it exists in locomotor ataxia. When, however, there is added a fragility, analgesia and ataxia, or analgesia alone, we may explain satisfactorily the course and the varieties of these joint complications.

They are presented to us under the picture of an arthritis traumatica, deformans, or neurogenica with its spontaneous fractures of the articular ends of the bones, and the excessive production of callus both by the periosteum and soft parts about the joint.

As a traumatic or deforming arthritis, it runs so latent a course, on account of the analgesia, that it is not recognized by the patient until crepitation, dislocation, or excessive exudation into the joint and soft parts in the neighborhood give evidence of it.

This is generally considered as the beginning of the process. It is spoken of as sudden in its onset, yet it has been present for a long time and remained unrecognized by the patient, on account of the analgesia. Should the injuries to the joint be slight and rest and care are given it, the course is benign, whereas the degree of injury, due to the analgesia, ataxia, and fragility of the bones, or any combination of them, stamp the course as malignant—*i. e.*, the rapid destruction of the articular ends of the bones, the tearing off of the ligaments, and the excessive production of callus extending to the soft parts, especially insertions of the tendons and muscles about the joint.

In general, however, the first symptom seen is an acute or subacute swelling of the joint and the neighboring tissues without a cause, and often during the night, without temperature elevation, redness of the skin, or constitutional disturbance. Such a condition may remain days, weeks, or months, and resolve in part; yet there remains a well-marked deformity in the joint with abnormal mobility. The articular cartilages are destroyed, the epiphyseal extremities of the bones become polished, worn away, or destroyed, and replaced by irregular bony masses. Crepitation, foreign bodies within the joint (bony, cartilaginous, and fibrinous coagula), a papillary and cartilaginous synovitis with the formation of extracapsular callus by the periosteum, tendons, and muscles, are the characteristic symptoms. These, when combined with the early symptoms of locomotor ataxia, syringomyelia, etc., render our diagnosis, prognosis, and treatment a certain one.

The deleterious influence exerted by these nervous disturbances upon the course of syphilis, tuberculosis, and purulent infections in joints is to be always considered in any prognosis.

It has been my intention in this paper to bring before the society nothing new—simply a statement of those diseases of the joints I find most difficult of diagnosis.

A thorough knowledge of the diseases causing joint inflammations and an accurate examination of the local condition is our only guide to treatment and prognosis. It is only when we make the diagnosis accurately that we can tell our patients of their curability or incurability. When this is accomplished, the means of cure, if any exist, are few and sufficient.

THE SIMULTANEOUS OCCURRENCE OF DISEASE OF THE HIP AND KNEE JOINTS IN THE SAME LIMB.*

By REGINALD H. SAYRE, M. D.

The simultaneous occurrence of disease in the hip and knee joints of the same limb is so rare that I have thought it worth while to report such a case to this Section, and to describe a new splint for the treatment of this complication. As the splint can be best described in connection with the case, I will briefly outline the latter:

R. McC., aged six years, had scarlet fever when two years old, followed by suppurating otitis on both sides, suppurating glands in the neck, and an ischiorectal abscess. About eight or nine months after the fever he had a very bad fall, soon after which he complained of severe pain in the right knee, which was then fastened in a felt splint and became apparently well after some time. Just as the knee became well he fell out of a carriage, and soon after had great pain in the right hip. He was then put to bed with extension applied to the right limb by means of a weight and pulley, and subsequently wore a long traction hip splint while walking for about a year, at the end of which time he seemed to be cured.

Some months after this the left knee began to swell and be painful, followed in turn by the right knee and left shoulder. These joints were wrapped in cotton and antirrheumatic reme-

* Read at the Tenth International Medical Congress Berlin, 1890.

dies given, the pain and swelling subsiding after a while, leaving the left shoulder, however, almost ankylosed.

In October, 1888, the right knee began once more to flex and give pain, and the right thigh became flexed on the abdomen, and at that time the child first came under my observation. He was pale and badly nourished. One ear still continued to discharge. The right knee was hot, swollen, and tender to pressure, and flexed at an angle of forty degrees. The right hip joint was flexed at an angle of forty-five degrees, and the adductor muscles were very rigid. When slight traction was applied to the thigh, limited movement of the hip joint did not cause pain.

He was put to bed and traction made on the diseased limb, as shown in Fig. 1.

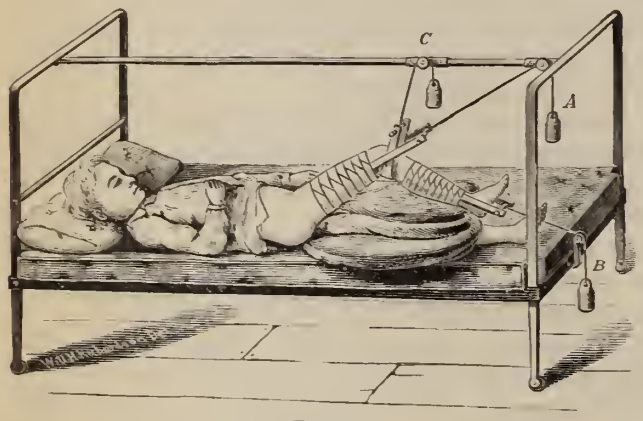

Fig. 1.

Adhesive plaster was fastened to the thigh, and by means of a weight and pulley (A) traction was made on the thigh in the direction of the deformity, the body being fastened flat to the bed. By means of other adhesive plasters fastened to the calf, a second weight and pulley (B) made traction on the knee joint in the long axis of the tibia, while a third weight and pulley (C), attached to a band passing behind the leg at the head of the tibia, made traction at right angles to the long axis of the tibia, thus overcoming the tendency to subluxation of the knee. After six weeks of this treatment the deformity was sufficiently reduced to permit the application of the splint, which I shall now describe, and which is a combination of the splints devised by my father many years ago for the treatment of chronic disease of the hip and knee joints when occurring separately.

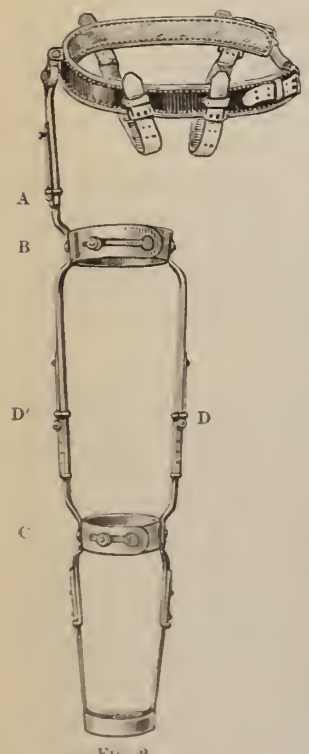

Fig. 2.

This instrument (see Fig. 2) consists of a pelvic belt with two perineal straps, which belt is fastened by means of a platform joint to a rod running down the limb to the ground. In the platform joint is a screw for making abduction of the limb if necessary. Below this is a ratchet (A) for elongating the rod. Attached to the outside rod are two steel collars (B and C), which encircle the thigh and calf, and which are connected together by a second rod running up the inside of the leg. Both inside and outside rods are furnished with ratchets (D and D'), to permit them to be lengthened. These side rods are continued below the calf collar to the ground, where they join together in a wooden shod foot-piece. To apply the splint, strips of heavy adhesive plaster, an inch wide and long enough to extend from the top of the patella to the groin, are put longitudinally all around the thigh (see Fig. 3) and tightly secured by a bandage, which is carried as high as the point

Fig. 3.

Fig. 4.

where the collar encircles the thigh. Similar strips of adhesive plaster, long enough to reach from the head of the fibula to the malleolus, should then be applied all around the calf, the bandage being carried from the knee down to the point where the lower collar encircles the calf (see Fig. 4).

The pelvic belt is now put around the pelvis and the collars brought moderately tight about the thigh and calf, and fastened, care being taken to place a pad on each side of the crest of the tibia to prevent chafing by the encircling collar. The adhesive plasters are now reversed over the collars, and held in place by another strip of adhesive plaster drawn tightly around the collars. A roller bandage is now applied to retain the ends of the reversed adhesive plasters in position. The thigh and calf being now securely fastened to the collars, traction can be applied to the knee by means of the ratchets (D, D'), the amount of traction being limited by the patient's sensations, stopping at the point that gives the greatest relief.

The knee must now be bound with strips of adhesive plaster to prevent swelling, and a tight roller applied over all. A bandage is then passed about the thigh, going over the thigh and under the side bars of the instrument to press the femur backward, and a second bandage is passed around the leg, going under the calf and over the side bars of the instrument to force the tibia forward, thus taking the place of the pulley C (Fig. 1). A bandage is applied to the foot to prevent swelling.

The knee having been adjusted, the pelvic belt is then

drawn tight, and the perineal straps are drawn sufficiently tight to bring the pelvis belt below the anterior superior spines of the ilium. By means of the ratchet A (Fig. 2), traction is made on the hip joint to the point of greatest comfort.

A shoe with high heel and sole is applied to the foot of the sound side to equalize the extra length caused by the projection of the splint below the foot of the lame side, the patient walking on the high shoe and the splint (see Fig. 5) and receiving the weight of his body on the perineal straps.

In the case under consideration the adhesive plasters have been changed four times since the splint was first applied in December, 1888—a period of about eighteen months. When removed last October the knee was much less tender and swollen than at first, but still sensitive to any movement.

When removed the next time, which was in June, 1890, the knee was straight and free from pain on movement, though evidently not thoroughly well. The hip had free movement and there was no muscular spasm.

Fig. 5.

The photographs do not show the knee as straight as it should be, having been taken just after the last application of the splint, the boy having been without it for ten days just before this, during the time the splint was being repaired, and the skin becoming hard after exclusion from the air for eight months. I had bent the knee somewhat also, and the flexor muscles were rather slow to relax. When I removed the splint, the knee was straighter than shown in the picture, and is now once more becoming straight.

It may be asked why I allowed motion at the hip and not at the knee. In this case limited motion of the hip joint did not give pain, provided slight traction was made on the thigh, and I therefore thought the child might be allowed the additional comfort of movement at the hip without harm; and the result has so proved. If motion of any sort had given pain in the hip, I should have immobilized that joint also.

The extension of the splints by its various ratchets and the changing of the bandages must be altered from time to time as the improvement in the joint, the slipping of the adhesive plaster, or the comfort of the patient demand.

HYDRASTIS, VIBURNUM, AND PISCIDIA IN DISEASES OF THE FEMALE ORGANS OF GENERATION.*

By REYNOLD W. WILCOX, M. A., M. D.,
PROFESSOR OF CLINICAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO THE DEMILT DISPENSARY.

The great interest that has been excited by every acquisition to the Pharmacopœia of drugs that have a therapeutic action upon the female organs of generation proves conclusively that the profession at large ask for more than merely surgical gynæcology. While the surgical methods of treating diseases peculiar to females have attained to a high standard and in technique leave but little to be desired, the requisite skill is by no means sufficiently widespread, nor indeed of low enough cost that all suffering women may be relieved. While our post-graduate schools are sowing broadcast the seeds of surgical gynæcology and imparting the results of their experience to physicians from all portions of this country, yet, nevertheless, there remains a large proportion of the medical profession who seek to relieve by methods other than operative. Further, it is notorious that a specialist seeks the shortest road to relief and is apt to ignore other, perhaps longer but certainly pleasanter and finally surer, methods of treatment. While I would not in the slightest degree belittle the brilliant surgical results of our foremost gynæcologists, yet I would submit that medical gynæcology has a very important place.

The past decennium has given us new drugs, new uses for drugs, and has firmly settled on a physiological basis the indications for the employment of certain drugs. In January, 1887, I read before the Alumni Association of the Woman's Hospital of New York a paper entitled Hydrastis Canadensis in Uterine Hæmorrhage, which was published in the *New York Medical Journal* under date of February 19, 1887. In this paper I presented the results of the employment of hydrastis in forty-three cases. The chief indication for its use is uterine hyperæmia, resulting in menorrhagia and metrorrhagia. Secondary results, such as endometritis fungosa, displacements, and permanent engorgements of the uterus, were naturally relieved by its use. The publication of this paper was followed by a greatly increased demand for the drug, its use by a large number of practitioners, and it has become one of the staple drugs of the pharmacy. When the diagnosis is well established and the drug is administered in accordance with the indications, success is as probable as with any other drug whose physiological action is well established. During my earlier studies certain disadvantages were found; menstruation was frequently suppressed, at times pains would be produced, although never the crampy pains of ergot, and all cases in which the amount of flow was below the normal were not relieved. Some of these were errors in administration; others were due to the peculiarities of the drug itself. Although in a chlorotic girl it might be well to produce cessation of the menses for a time, yet the mental disturbance of emansio mensium is generally unadvisable. The best

* Read before the Clinical Society of the New York Post-graduate Medical School and Hospital, November 29, 1890.

results were obtained in cases of chronic hæmorrhage due to inflammation of uterine tissue, circumuterine inflammations, and also in displacements due to engorgement.

The abominable taste of the fluid extract of hydrastis was never concealed, and it was only possible to continue its administration when the results obtained were so excellent as to make its exhibition a necessity. Earlier experiments with the alkaloid hydrastine showed that the alkaloid did not fully represent the drug. In the present year the observations of Falk with an oxidation product of hydrastine, which is known as hydrastinine, have shown that, so far as menorrhagia, metrorrhagia, congestive dysmenorrhœa, and endometritis are concerned, it seems to act as well as the fluid extract. The dose is three quarters of a grain hypodermically. Its present great objection is the price.

Viburnum, since its introduction to the profession by Jenks, nearly fifteen years ago, has held its own as a remedy for dysmenorrhœa against many drugs then lauded to the skies, but now long forgotten. It will certainly relieve dysmenorrhœa if the testimony of thousands of intelligent physicians is worth anything. In the nervous phenomena of the climacteric it will diminish reflex activity, acting in precisely the same lines as the bromides, but without the great general depression of their long-continued use. Alone it is not sufficiently sedative to relieve pain, as is shown by the following case, when more markedly antispasmodic remedies—such as hyoscyamus, cannabis indica, camphor, conium, and avena sativa—must be employed:

Miss S. M., aged eighteen, first seen on March 26, 1890. Duration of illness, four years. Complains of poor appetite, but the bowels are regular; the tongue is pale and flabby; anæmic murmur in neck. Menstruation at thirteen, always irregular, every four to seven weeks, lasting one or two days and scanty. Has severe pains in groins and back for twenty-four to thirty-six hours before flow; pain is constant and sharp, alternating with cramps and dull pains. Has much neuralgic headache during periods. Has passed clots on several occasions, but without relief of pain. At times has fainted. Tenderness over lower abdomen quite marked. Diagnosis: congenital anteflexion, undeveloped uterus. Ordered fluid extract of viburnum, thirty drops every two hours during attack; concentrated tincture of avena sativa, twenty drops in hot water during crampy pains every twenty minutes until three doses are taken. Hot-water bag to abdomen; turpentine enemata. Hot sitz bath during day preceding flow. Bed during menstruation.

April 28th.—Flow greater in amount and pain much less. Viburnum alone does not relieve pain so much as when avena sativa is given with it.

June 12th.—Last period was a great improvement upon the preceding, due probably to the free administration of iron in the interval. Also did not suffer from neuralgic headaches. Is going into the country.

September 22d.—Last two periods have been almost entirely free from pain. Has taken iron faithfully since last report.

That viburnum is markedly sedative, so far as the uterus is concerned, is shown that, if used after labor, it is one of the best remedies for post-partum pains, provided that they are not of mechanical origin. Deficient menstruation is not so great a bar to the employment of viburnum as it is to that of hydrastis. On the other hand, viburnum has a far more beneficial influence upon the heart and upon the general nutrition than hydrastis has.

Piscidia as a hypnotic attracted much attention about ten years ago. My own experiments were unsatisfactory, and other drugs have supplanted it as a hypnotic. Yet Ott's investigations in the physiological laboratory show that piscidia has a well-defined action, and, in connection with other drugs, undoubtedly has its use. Ott found (1) that piscidia was narcotic to frogs, rabbits, and men; (2) did not affect the irritability of the motor nerves; (3) did not attack the peripheral ends of the sensory nerves; (4) reduced reflex action by a stimulant action on the centers of Setchenow; (5) produced a tetanoid state by a stimulant action on the spinal cord, and not by a paralysis of Setchenow's centers; (6) dilated the pupil, which dilatation passed into a state of contraction upon the supervention of asphyxia; (7) was a salivator; (8) increased the secretion of the skin; (9) reduced the frequency of the pulse; (10) and increased arterial tension by stimulation of the monarchical vaso-motor center; (11) that this increase was soon succeeded by a fall, due to weakening of the heart itself. Piscidia, in medicinal doses, produces muscular reaction, lowered sensibility, increased action of the heart, and increased arterial tension through stimulation of the vaso-motor center. Through its action on the muscular system it can supplement viburnum and neutralize hydrastis in spasmodic dysmenorrhœa. In all painful diseases of the uterus and annexæ it is of service through its power of lowering sensibility.

For the last year I have been experimenting with a preparation known as liquor sedans, manufactured by Parke, Davis, & Co., which has the following formula: Hydrastis, 60 grains (represented by the white alkaloid); viburnum, 60 grains; piscidia, 30 grains, to each fluid ounce of the preparation. The drugs are combined with aromatics so that the mixture is not unpalatable, and presumably these additions have some therapeutic effect. The cases in which I have made use of this formula have been those in which an operation was not possible, either because the patient's consent could not be obtained, or the patient could not be kept under control. Nor have I inserted cases in which local treatment was the most important feature. While all of these cases were under observation and reported from time to time, yet none of them had regular local treatment, because, for various reasons, it was not possible.

Case I.—Mrs. D. G., thirty-five years old, has been sick for the last six years previous to the time when she was first seen in 1886. She complains of general debility, failure of health dating back to childbirth, with times of improvement. Thin, anæmic, of sanguino-bilious temperament. She has poor appetite, sometimes an accumulation of gas, discomfort after eating, pain in stomach and bowels, distention, rarely nausea, flatulence, constipation, suffers from hæmorrhoids, pain about heart, sometimes palpitation, occasionally faintness and shortness of breath without exertion. No cardiac or pulmonary physical signs. Sometimes has stoppage of urine for twelve hours; at times has frequent urination, every half hour, especially when tired; color of urine varies much. Has pain in loins.

The catamenia have always been accompanied by great pain

during her entire menstrual life, profuse, lasting seven days, with cramps and clots, and much foul-smelling vaginal discharge. Has had one child, six years ago. Her pains occur five days before the flow appears, in back and sides, especially the left; worse on exertion. Has vertigo, neuralgia, sick headaches, chilly sensations. Great tenderness on percussion over eighth dorsal vertebra. Interrupted sleep. On examination, the vesico-vaginal septum is found to be hard, the cervix, with laceration to the right, soft, except at site of tear, which is hard and sensitive. Some cervical cysts, tenderness on the left side of the uterus, which is in good position. Some thickening in utero-sacral ligaments, but not especially tender. Laceration of perinæum with sensitiveness on examination. Urethral opening reddened. Some carnunculæ, very sensitive. Diagnosis: subinvolution of uterus, anteversion, hypertrophy of urethral mucous membrane. During the next six months she improved greatly under a small amount of local treatment, spending her summer in the country. Excessive flow was controlled by the fluid extract of hydrastis, and her general condition was improved by diet, tonics, and general medication. After about three years of comparative comfort she reported on January 19, 1890, that her symptoms had recently become much aggravated and that she was in nearly the same condition as in 1886. Liquor sedans, one drachm in water, three times daily for two months, was ordered.

May 12th.—Has had much less pain in back and left side since last report. Uterine leucorrhœa much improved and vaginal discharge much less; the amount of menstrual flow has diminished about one half. Feels much improved both in general health and in regard to urinary symptoms.

October 1st.—The gain has been permanent; although not well, does not think that medication is necessary.

Case II.—Miss S. A., aged twenty-two, was first seen on July 13, 1889. Has been sick for the last six years, complaining of fits. General surroundings good. Digestion perfect, excepting occasional constipation due to improper food; rarely suffers from palpitation of the heart; occasionally frequent urination, especially at time of periods. Catamenia at fifteen, regular, with normal flow. Preceding are pains in back and groins. During flow has fits, falls, sometimes localized convulsions; no frothing at mouth or biting of tongue; is sleepy after attacks, during which she loses consciousness. Has never injured herself during fits. Has no warning of impending attack; eyes are always closed. At times has had opisthotonos, but never general rigidity or general convulsions. Attacks have grown worse during the last two years, and occasionally has fits of lesser severity in intermenstrual period; is always of good temper and not hysterical. Diagnosis: anteflexion, ovarian hyperæmia, hystero-epilepsy. Ordered to take liquor sedans for one week before and during menstrual flow, one drachm three times daily; to use plain food, avoid all fried food, tea, coffee, cake, candy; use oatmeal and plenty of fresh fruit: avoid stimulants; to have hot-water douches.

September 30th.—Has had four attacks since last report. Ovarian sensitiveness less marked. Ordered to take liquor sedans constantly.

December 22d.—One marked and two slight attacks; anteflexion is persistent, but canal admits a probe easily. To take liquor sedans only during menstrual flow.

June 6, 1890.—To-day has had her first severe attack since last report. Has been menstruating with less pain than for two years. Ordered liquor sedans for two months.

September 25th.—Has had but one slight attack since last report; uses liquor sedans only during flow.

Case III.—Mrs. H. A. H., aged twenty-four years, had been ill for three months before she was first seen on May 17, 1889. The cause of her illness was overwork before complete recovery from parturition. She complains of poor appetite, constipation, pain on movement before the act, relieved by the passage. Rarely dizziness; sometimes palpitation of the heart. Slight cough, but no expectoration; no physical signs to be found in the chest. Frequent urination; color of urine varying; sometimes pain and smarting during the act; nothing abnormal found on chemical or microscopical examination. Menstruation regular every three weeks, lasting five days, profuse, followed by illy-smelling uterine and vaginal leucorrhœa. Has had one child, eighteen months old. Has also pain in the legs; feels as though "she would fall to pieces" on walking; pain on rising from a sitting position; headaches. Diagnosis: anteversion, purulent endometritis, exudation into left broad ligament, catarrhal urethritis, subinvolution of uterus. Ordered liquor sedans, one drachm four times daily; Fowler's solution with the bromides; full diet with full Emmet douche twice daily.

June 7th.—Much less uterine pain; induration of left broad ligament has diminished.

August 7th.—Has now no vaginal discharge; pain much lessened; uterus now nearly normal in size; can walk much better. Catamenial flow much lessened. Is now to use liquor sedans only during flow.

December 29th.—General health has much improved. Anteversion still remains, but, beyond some tension on the neck of the bladder, does not annoy the patient.

April 25, 1890.—Patient now considers herself much improved and uses liquor sedans only when flow exceeds the normal. Has no vesical symptoms. Has gained about fifteen pounds in weight.

September 26th.—Patient reports that she is well.

Case IV.—Mrs. C. W. O., aged thirty-five, was seen on January 6, 1890. Had been ill for three years. Her previous sicknesses had been catarrhal otitis media, resulting in deafness, and acute peritonitis. She complained of inappetence with marked constipation when enemata were not employed, faintness, dizziness, tinnitus, frequent urination when fatigued. Catamenia at fourteen, recurring every four or five weeks; generally scanty flow, which lasts three days. Of late, during last two years, has unexpected attacks of flooding, losing large amounts of blood, these attacks being only at or about the normal menstrual periods. Has much constant pain in back, dragging pains on standing or much walking. Some glairy discharge from the vagina. Traces origin of present attack to peritonitis following excessive tamponade, when she was confined to the bed for three weeks. Diagnosis: pelvic peritonitis, lateroflexion of uterus, induration of left broad ligament. Ordered Fowler's solution, to have liquor sedans, one drachm four times daily, during periods, nourishing diet, Emmet douche, bed during menstrual epoch.

March 20th.—Patient takes her medicine with considerable regularity, but as regards douche leaves much to be desired. The exudation in the broad ligament has diminished as well as the tenderness.

July 3d.—A fair amount of improvement in her general condition, with but little change in local state since last report.

October 15th.—Patient professes great benefit from remedy.

Case V.—Miss W. S., aged thirty-three; when first seen on September 3, 1889, complained that she had suffered for ten years from dysmenorrhœa. Always well at other times excepting slight headaches. Appetite good, with excellent digestion and regular bowels. Painful and frequent urination only during periods. Menstruation at thirteen, always regular. During the last ten years her periods have become more and more painful. The pain commences, about thirty-six hours

before the flow, in the back, groins, and in front, sharp, and obliging the patient to take to her bed, with severe cramps. The flow then begins and is scanty at first, giving some relief to the pain. It then increases in amount, and much pain is followed by expulsion of clots. The flow lasts three or four days, and recurs every twenty-eight days. Severe frontal headache during first two days of flow. Some cervical leucorrhœa. Diagnosis: congenital anteflexion, retroversion of the third degree, some prolapsus. Ordered to take liquor sedans, one drachm four times daily for week before and during menstrual flow. Fothergill's pills should the flow be delayed; nourishing food, outdoor exercise.

January 2, 1890.—Periods are more tolerable, but still less pain; uterus in good position as regards version and prolapsus.

March 7th.—Of late the remedy seems ineffectual; passed sound, and dilated internal os.

April 12th —Last period with much less pain, no headache, and was not confined to her bed.

June 27th.—Last two periods passed with much less than usual pain. Application of carbolic acid made to endometrium. Canal patent, and there is no leucorrhœa.

September 20th.—Last period practically painless while using liquor sedans.

Case VI.—Miss S. H., twenty-eight years old, after an illness of two years was first seen November 24, 1889. Her lips are pallid; is troubled with atonic dyspepsia, constipation and considerable abdominal pain, faintness, dyspnœa on exertion, anæmic bruit in vessels of neck. Frequent urination at times of period, but no pain. Menstruation commencing at fifteen, is regular every four weeks, and lasts three days. Of late recurs every fourteen to twenty days and lasts a week, with profuse flow; vaginal leucorrhœa. Pain in loins and back. Diagnosis: menorrhagia; retroversion, second degree. Ordered liquor sedans, one drachm four times daily for week before and during menstrual flow. Daily movement of bowels to be secured by hygienic methods.

December 30th.—Result good; interval is lengthened to twenty-eight days, and flow is nearly normal.

February 19, 1890.—Time of flow, three days; amount is normal, and now has no pain.

Case VII.—Miss S. M. P., aged twenty-five, was first seen June 2, 1889, after an illness of four years. She is anæmic, suffers from neuralgia and emansio mensium of six days' duration. Complains of inappetence, headache, fullness of head, throbbing in temples, palpitation, frequent urination. Menstruation irregular, recurring every four to six weeks, lasting four days, with small amount of flow, cramps, and clots; color pale. Pain in back and loins, extending down sciatic nerves. Headache at the vertex. Diagnosis: congenital anteflexion with retroversion of first degree. Ordered to take Fothergill's pills during premenstrual week, and one drachm of liquor sedans during flow.

June 24th.—Is much improved as regards pain during her last period. Flow still scanty, but did not pass clots.

February 1, 1890.—Is still anæmic, but periods are passed with comparative comfort.

June 5th.—A severe fall is followed by abdominal tenderness, much uterine colic, and considerable pain extending down both sciatic nerves, more marked, however, upon the right side. Retroversion is now of the second degree. Colic is relieved by twenty-drop doses of concentrated tincture of avena sativa every half hour in hot water.

20th.—Is passing through period with less than usual pain. Retroversion reduced by position. Complains much of sleeplessness, for which chloralamid in twenty-grain doses is ordered.

30th.—Greatly improved; chloralamid is to be omitted. To use liquor sedans during the flow.

September 29th.—During her stay in the country has greatly improved. Periods are now painless while using the remedy.

Case VIII.—Mrs. M. J. N., aged twenty-nine, was first seen on June 1, 1889; has been under great mental strain for several months. She was suffering from palpitation of the heart, faintness, vesical tenesmus, frequent urination at times of her period, poor appetite. Her conjunctivæ were yellowish, liver dullness enlarged, edge rounded, with some hepatic sensitiveness. Constipation, pain in back, groins, and thighs, cramps, and bearing-down pains. Catamenia regular but profuse, backache worse on walking, slight vaginal leucorrhœa. Has also vertigo, insomnia, and general nervousness. Diagnosis: anteversion, laceration of cervix, and cystic degeneration of the same caused by a miscarriage three years previously. Ordered to take liquor sedans, one drachm three times daily, with thirty grains of sulphonal after dinner. Full diet. Emmet douche.

June 16th.—Has fewer cramps and less backache; urination nearly normal, frequent only when much upon her feet.

September 30th.—To use liquor sedans only during menstruation.

February 16, 1890.—Menstruation nearly normal in amount. Constipation relieved by Villacabras water.

May 23d.—Has gained ten pounds in weight; sleeps without drugs.

September 20th.—Considers herself well.

Case IX.—Mrs. A. J., thirty-five years old, was first seen on March 5, 1890. She had been ill for three months, complaining of neuralgic headaches. Bowels moderately regular. Catamenia at fifteen. Has had two children and several miscarriages. During the past three months her menstruation, although usually regular in time, has recurred every twelve to fourteen days and has lasted four days. This flow is profuse and is accompanied by fainting. Pain in the back is very marked during flow; at times pains in groins; some vaginal leucorrhœa. Diagnosis: laceration of perinæum of the second degree, laceration of cervix, retroversion of first degree, slight prolapsus, granular endometritis. Ordered to take liquor sedans, one drachm thrice daily. Emmet douche.

April 6th.—Flow now recurs every three weeks and is less in amount. No more fainting attacks. No leucorrhœa.

June 25th.—Is now in good condition. Prolapsus relieved.

July 20th.—To omit medication except for three days before flow.

October 21st.—Flow normal and pains very slight.

Case X.—Mrs. R. H. E., aged thirty-five, was seen on December 30, 1889. Her sickness dates back three months. Is somewhat nervous, has slight choreic twitching of the face, rarely attacks of atonic dyspepsia. Bowels move regularly every day. Complains of frequent urination, especially after standing or walking. Has had several miscarriages and one living child, now three years old. Catamenia at thirteen, always regular, recurring every four weeks, generally profuse, and lasting five days. For last three months has noticed a yellowish-white vaginal discharge, which has increased in amount. Has considerable pain in the back, worse on walking, when she easily gets tired. Some increase in the amount of menstrual flow. Pain in back worse during periods. Diagnosis: retroversion of the second degree, catarrhal endometritis, cervical leucorrhœa. Ordered to take liquor sedans, one drachm thrice daily, constantly. Emmet douche, with alum.

January 19, 1890.—Vaginal discharge has markedly diminished; no pain in back; retroversion relieved by tamponade.

March 17th.—Patient much improved in general health; flow normal in amount, and has now no leucorrhœa; uterus is in good position.

September 2d.—Has returned from the country in excellent condition.

Case XI.—Mrs. W. V. P., aged thirty-two, was first seen on May 24, 1889. She is thirty-two years old and has been ill for six years. She complains of dizziness and faintness at times, but rarely of palpitation. Has a considerable amount of cervical leucorrhœa. Catamenia regular every four weeks, lasting eight days and very profuse, with cramps and clots; pain in the back, worse on walking; sometimes pain in the groin for two days preceding flow. Headaches, especially at times of period. Diagnosis: endometritis simplex, anteflexion, retroversion of first degree, with small uterine fibroid in anterior wall. Ordered liquor sedans, one drachm four times daily. Emmet douche.

May 27th.—Outerbridge's dilator inserted. Cervical leucorrhœa somewhat diminished in amount. Cervical canal will admit a uterine sound without difficulty. Uterus is in the normal position.

October 15th.—Now has no more cramps, and rarely clots; flow much diminished in amount. Takes liquor sedans only during period.

December 6th.—Periods are now at full time and occasionally a few days beyond.

April 7, 1890.—Has now no pain. Cervical canal patent; general health much improved.

September 12th.—No pain or vaginal discharge; is in excellent condition.

In the recording of these cases I have endeavored to give a faithful picture and an accurate report of the results. From these we may say that in all cases of hyperæmia of the female reproductive system we have in liquor sedans a safe and reasonably sure remedy. In many spasmodic diseases and in a few cases of anæmia of these organs we find the remedy also indicated. It certainly has a wider field of usefulness than any single drug, and, if used after a careful diagnosis is established and after thorough appreciation of the pathological conditions that exist, we can anticipate a successful issue so far as improvement is possible from purely medical methods.

690 Madison Avenue, *October 31, 1890.*

Correspondence.

LETTER FROM NEW HAVEN.

The First Koch Inoculations in America.

New Haven, *December 8, 1890.*

On Thursday, December 4th, the people of this usually quiet and somnolent town were aroused by the announcement in the morning papers that a small quantity of Koch's "lymph" for the cure of tuberculosis had been received by Professor Chittenden at noon of the preceding day; that Professor Chittenden, desiring that it should be used for scientific study, and not being himself engaged in practice, had intrusted it entirely to Dr. John P. C. Foster for experimental investigation; that on the preceding afternoon Dr. Foster had administered an injection of it to a patient with pulmonary tuberculosis; and that, on the afternoon of the day on which the announcement was made, an injection of the precious fluid was to be given to one of Dr. Swain's patients who was suffering with tubercular laryngitis, and to a subject of lupus who was a patient of Dr. Francis Bacon's.

The interest in the matter has not been confined to New Haven, if one may judge from the eagerness with which the newspapers of the large cities have tried to learn all the details, and from the prominence that has been given to the accounts of the experiments. Doubtless many a physician as he has read these accounts has wondered how it happened that Koch, who is reputed to have been so very careful as to whom he trusted to make trial of his curative "lymph," should have sent a sample of it to New Haven, rather than to New York, Philadelphia, Boston, or Baltimore, or even to Chicago, Cincinnati, or St. Louis. Some may have been surprised that it was received by Professor Chittenden, a physiological chemist, rather than by a pathologist like Welch or Prudden, and that it fell into the hands of a physician whose name they had never seen attached to an article in any of the journals, rather than into the hands of distinguished clinicians and authors like Delafield, Janeway, Loomis, or Trudeau. But to the physicians of New Haven, among whom the facts are gradually becoming generally known, the arrival of the wonderful "lymph" seems less strange now than it did last week. It happened in this way. A resident of this city, a Mr. Blake, has a son who is (or at least was before being subjected to the Koch treatment) critically ill with pulmonary tuberculosis. Mr. Blake read of Koch's discovery, and concluded that he would like to have it tried upon his son. Professor Chittenden was persuaded to endeavor to obtain some of the fluid. He is a personal friend of Professor Kühne's, of Heidelberg, and from Heidelberg a small quantity of the liquid, which—by special messenger, the newspapers state—had just been brought from Berlin, was sent to Professor Chittenden. Dr. Foster is the young man's physician and also his relative. It was therefore very natural that the use of the "lymph" should be intrusted to him.

Fortunately, Dr. Foster, although he does not contribute to medical periodicals and seldom takes an active part in the proceedings of medical societies, and therefore has not a very wide reputation (or did not have before his name became associated with that of Koch), is nevertheless a very excellent practitioner. He is a man of good education, having been graduated from the academical department of Yale University in 1869, and from the medical department in 1875. He is instructor in anatomy in the Yale School of the Fine Arts and acting assistant surgeon of the United States Marine-Hospital Service. He belongs to one of New Haven's old families, and one of considerable social prominence. He is refined and affable in manner, and moves in the best society. He does an active and lucrative practice, especially among students and families of wealth and social and intellectual distinction. Altogether he is not such a man as one would expect to make any great discovery in the dead-house or the laboratory, perhaps not such a one as Koch himself would have selected to make the first trial of his new treatment in America, but nevertheless a very good man for this latter work, because he is possessed of sufficient scientific training and intelligence to be able to observe anything worth noting in connection with the action of the remedy, and because he is not likely to be prejudiced by any preconceived notions in regard to its value.

Of the practical results of the treatment as applied to the patients in New Haven it is still too early to speak, inasmuch as but five days have elapsed since the arrival of the remedy. Enough has been written to explain why it happened to be received in New Haven, and to show that the investigations here are being conducted by a competent and careful practitioner.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, DECEMBER 13, 1890.

VIVISECTION.

We spoke last week of the public notice that had been taken of an attempt made in one of the city hospitals to fill a gap in a boy's tibia with a piece of bone from the leg of a dog, and expressed our regret that it should have been made the subject of sensational reports by some newspapers and of unsparing condemnation by others. The interests that may be imperiled by such experiments and by such notice of them are so important that a word of warning seems to be called for. Twenty-five years ago the antivivisection agitation was very active, and resulted in the passage, in 1866, by the New York Legislature, of the law under which we are now living. It is a law not only with which we may be satisfied, but of which we may well be proud, for it gives ample protection to animals and at the same time to properly conducted scientific research. It was the result of the efforts of the late Mr. Bergh, the honored president of the Society for the Prevention of Cruelty to Animals, acting in behalf of the animals, and of the late Professor Dalton, acting in behalf of the interests of science, and under it these two interests, which in many other regions are in permanent and irreconcilable hostility to each other, have here continued in peace and mutual respect.

But with the passing years there has come a generation "that knew not Joseph," a generation that is ignorant of the circumstances connected with the making of the law and, what is worse, even of the restrictions imposed by it.

Most physicians appear to be ignorant of the fact that the law *prohibits experiments upon animals*, and makes an exception only in favor of "properly conducted scientific experiments or investigations . . . under the authority of the faculty of some regularly incorporated medical college or university of the State of New York." We know it to be true of some of our medical colleges, and we believe it to be true of all, that they have fully appreciated their responsibility under this law and have been exceedingly circumspect and chary in extending the opportunities thus placed under their control. But many such experiments have been made without such authorization and apparently without a suspicion that it was required, and their details and results have been freely published.

On the other side there are men and women who are ignorant of the agitation of twenty-five years ago and of the honorable agreement then reached, and who are inexpressibly wounded and shocked by the reports of acts that seem to them, and, it must be admitted, often with reason, to have been the cause of atrocious suffering without an adequate return. Many of them feel it a personal responsibility before God and their consciences if such practices are allowed to continue, and it can not be doubted that the feeling will ultimately take shape in action. We must even admit that it is right that it should. As a profession, we have taken a clear and positive stand in the matter. We were represented in the discussion that preceded the enactment of the law by some of our most honored members, and we supported them by formal resolutions passed by various county societies—resolutions that have been passed again and again whenever the agitation was renewed. If now individual members of our body have sinned against the law, against a law that we have accepted as just and fair, we must repudiate their acts and throw the responsibility upon the individuals and upon those who are charged with the enforcement of the law, or we must prepare again to fight against the hasty and emotional legislation that will surely seek enactment.

We are not referring specifically to the boy-and-dog experiment. That may or may not have been judiciously conceived and properly executed. Whether or not a graft from a dog to a boy is likely to succeed after a graft from the boy to himself has failed, and whether or not the radius of a dog may be an efficient substitute for the tibia of a boy, are questions upon which opposing opinions may perhaps be honestly held. We believe the surgeon was making a sincere attempt to benefit his patient. We also think the operation should be classed as a therapeutic measure, and not as such a vivisection experiment as was contemplated by the law. But it has been attended by so much notoriety that it may well prove the starting-point of an agitation greatly to be deplored—one from which our colleges, our laboratories, and our science might receive serious harm. To meet it we must put ourselves clearly in the right. It will not do to disclaim responsibility; we are responsible for the maintenance of a public opinion within the profession that will aid the law by frowning upon its infractions and by demanding a serious, thoughtful, and thoroughly scientific basis for any investigation that may cause suffering to even the most friendless brute.

MINOR PARAGRAPHS.

THE PROGRESS OF THE KOCH TREATMENT.

Koch's alleged remedy for tubercular disease is now being tried diligently in various parts of the world, but naturally the experiments in Berlin continue to be the greatest subject of popular and professional interest. The reports from that city indicate that the foreign physicians who went there to learn something about the matter are beginning to realize that they might as well have stayed at home. Specimens of the liquid have been received in New York and in New Haven, and its employment in New Haven has been under way for several days. One of the subjects of the experiments is said to be a person somewhat advanced in pulmonary phthisis, so that, as regards his case, a fair test of what Koch alleges for the remedy is hardly to be expected. As to the experiments in Europe, the fragmentary reports received concerning them do not seem to us to establish anything, except that the febrile reaction described by Koch does actually take place. It must be months yet before sufficient data can be obtained to settle the question of the curability of tuberculous disease by the Koch treatment —before, in fact, we shall know whether to class Koch's discovery with that of vaccination or with that of "gleditschine."

The experiments in New York were begun on Wednesday of this week; at St. Luke's Hospital by Dr. Kinnicutt, and at Mount Sinai Hospital by Dr. Jacobi. Both these gentlemen have the entire confidence of the profession, and the conclusions they report will have great weight.

OSTEOMALACIA IN CHRONIC DISEASE OF THE CENTRAL NERVOUS SYSTEM.

Dr. J. C. Howden, in the *Glasgow Medical Journal*, reports a case of mania followed by hyperæsthesia and osteomalacia. The post-mortem examination revealed softening of all the bones of the body except those of the skull. During the course of the disease there had been great pain and hyperæsthesia, which kept the patient constantly in bed, masking the mollities ossium, which was not detected until the autopsy. Dr. Konstantinovsky, in the *Medical Chronicle*, also contributes a monograph on this subject. The material for his study was derived from examinations of the dead bodies of patients who had suffered for varying periods with insanity in some of its forms. Twelve of them had had progressive general paralysis; four, dementia of various forms; two, imbecility; four, acute or chronic hallucinations; one, brain tumor; one, spinal myelitis; and two, endocarditis and tuberculosis. The last two were examined only casually. The chemical constitution of the ribs, the degree of their brittleness, the macroscopical peculiarities, and the histological characteristics were all inquired into. In summing up the results of his work the writer was of the opinion that in chronic disease of the nervous system, especially insanity, the ribs were apt to undergo very morbid changes, giving rise to brittleness, and hence a predisposition to fracture from the slightest violence.

SECTIONALISM IN MEDICINE.

In a recent discussion on intestinal anastomosis, at a meeting reported in the *Toledo Medical and Surgical Reporter*, one of the speakers mentioned a New York surgeon as objecting to Senn's plates, and as maintaining that the artificial channel of communication would contract so as to cause obstruction anew. The speaker added that he did not agree with the New York surgeon, and proceeded to class him with other surgeons of the East, who would not give credit for or place faith in anything that emanated from "the rowdy West," simply because the surgeons of "the rowdy West" did not "bend the knee often enough before the arrogant, self-conceited, autocratic, and jealous Eastern surgeons." This fraternal language followed upon this statement by the speaker: "Dr. Senn has been a great gleaner, and has received much credit for the ideas suggested by Connel and others." Dr. Senn lives farther west than Toledo, and perhaps he may look upon the Toledo censor as "arrogant, self-conceited, autocratic, and jealous," and be disposed to account for the fact by his not having bent the knee often enough before him. The remarks in question were, of course, only an exhibition of the speaker's individual spleen. There is no sign in the report that their spirit was entertained by anybody else present at the meeting, and we feel sure that those who cherish it, whether they live in the East or in the West, are few in number and utterly without influence to spread their offensive sentiments.

PAGET'S DISEASE OF THE BREAST.

Before the Northumberland and Durham Medical Society, at the meeting of October 9th, Dr. Hume exhibited a series of sections illustrating the pathology of Paget's disease of the breast, an account of which appears in the *British Medical Journal*. The clinical history of the case from which the sections were taken was peculiar from the fact that the enlargement of the axillary glands and the nodule in the breast had developed at the same time. From microscopical study of the sections Dr. Hume was of the opinion that the affection of the nipple was closely allied to, if not identical with, epithelioma; that the milk-ducts were dilated and disclosed an overgrowth of their epithelium, which took the form of tufts or villi; that the nodule in the breast showed an inflammatory small-celled exudation, and also groups of ducts and acini in which the epithelium was proliferating; and that the enlarged glands showed small-celled infiltration and cancerous structure. He concluded that the growth at the nipple had from the beginning been cancerous, and that it had spread downward into the ducts; that subsequently it had burst through the ducts into the stroma and become an ordinary cancerous nodule. He therefore recommended that in all cases of obstinate eczema of the mamma the breast should be amputated at once and the axillary glands enucleated.

COLCHICINE POISONING.

Dr. Millot-Carpentier, in the *Union médicale*, gives an account of a case of poisoning with this drug, a report of which Dr. Giulio Sprega recently published in the *Gazzetta degli ospitali*. Cotoine had been ordered for the patient, who had been a sufferer for several years with chronic intestinal trouble. By mistake, colchicine was given. Alarming symptoms of violent gastro-intestinal irritation soon followed; the pulse failed rapidly, there were involuntary stools and constant vomiting, and death occurred in four hours, notwithstanding every effort being made to control the symptoms. Before death the skin became insensible to the faradaic current. The autopsy revealed cutaneous emphysema, diffuse fatty degeneration of the liver, and mitral insufficiency. Under the mucous membrane of the stomach there was a blackish material, and in the intestinal canal there was a marked inflammatory condition with hæmorrhagic spots.

THE DEATH OF THE SURGEON-GENERAL.

The Surgeon-General's illness has terminated fatally, as we feared would be the case when we were closing up our last week's issue. Without questioning the wisdom and beneficence of Divine Providence, we feel that in expressing our own deep regret at General Baxter's sudden death we but give voice to the general feeling of the medical profession. His tenure of office was brief, and in the natural order of things it could not have been very much prolonged, but there was abundant ground for hoping that it would prove sufficient for the accomplishment of much work for which he was peculiarly well fitted, both naturally and by his training in subordinate offices. The army has been deprived of an excellent chief medical officer, and the medical profession has lost one of its brightest ornaments.

THE SOCIETY OF THE ALUMNI OF CHARITY HOSPITAL.

At a meeting, held on the 9th inst., Dr. Newton, of Montclair, N. J., presented a specimen, considered to be one of myxo-adenosarcoma, from the uterus of a woman eighty-two years of age. Dr. Brooks Hughes Wells read a paper on Perimetric Inflammations, in which he took the ground that no man suffering from even the slightest gleet should marry, because of the danger of infecting his wife and causing pelvic trouble. An animated discussion followed, which was participated in by Dr. Clement Cleveland, Dr. D. Bryson Delavan, Dr. W. L. Carr, Dr. J. B. Bissell, and others.

CORTICAL EXCISION IN THE TREATMENT OF PSYCHOSES.

Five cases of varied forms of chronic insanity are reported by Dr. Burkhardt in the *Internationale klinische Rundschau* as having been treated by removal of a portion of the cortex of the left frontal convolutions in three cases, and of the left parietal in two. There was marked amelioration of the violent symptoms, with an improvement in the mental condition in all but one of the patients. In that case the greater part of the cortex of the left parietal lobe was removed. Word-deafness followed the operation. The author is confident that the bad result in this case was due to carelessness in the operation.

PROTOPINE.

In the *British Medical Journal* there is a description of a new alkaloid with this name, derived from opium, but existing in very minute quantities. It has a formula of $C_{20}H_{19}O_5$, and was first isolated by Hesse in 1870. Further researches have detected it in the *Macleya cordata* and the *Chelidonium majus*, plants belonging to the natural order *Papaveraceæ*. Dr. von Engel, in the *Archiv f. exp. Pathologie*, describes the action of protopine on frogs. In small doses it had a narcotic action, while larger quantities acted as a poison to the voluntary muscles and to the motor nerve terminations, thus greatly obscuring any symptom of increased reflex action. The heart was slowed and weakened and the circulation much depressed, but there were no prominent symptoms of any action on the respiration.

INFECTION FROM MILK.

In the *Glasgow Medical Journal* for October there is reported an epidemic of sore throat and erysipelas occurring only in families that were supplied with milk from a certain farm. The most striking symptom was an intense inflammation of the fauces, resembling erysipelas of the mucous membrane, with swelling of the glands of the neck and in some instances suppuration. In some cases true erysipelas of the skin developed. The temperature ranged from 102° to 105° F. during the first few days of the attack. Convalescence was marked by extreme prostration. No bacterial examination was made, but a clear connection was traced between the milk and the epidemic.

A TREATMENT OF CHOLERA.

A simple method of treating this very formidable disease is given in the *Indian Medical Gazette* by Dr. Harkin, who says he has proved its value in a number of cases. The method consists in the application of a blistering fluid behind the right ear, with the view of stimulating the vagus nerve so as to inhibit the action of the sympathetic on the abdomen. The fluid, any epispastic, is applied with a camel's-hair pencil behind the ear and extending in the course of the pneumogastric nerve as far as the angle of the lower jaw. The result is at once apparent; the purging and other characteristic symptoms cease and the patients fall asleep long before vesication takes place and awake cured, or at least tided over the dangerous period.

THE TREATMENT OF CONDYLOMATA.

Dr. G. Finco (*Gazzetta medica lombarda*, June 21, 1890) employs a mixture of one part of corrosive sublimate and ten parts of collodion. The whole should be placed in a small bottle and well shaken in order to insure a minute division of the insoluble corrosive sublimate. The larger condylomata are first touched, a camel's-hair pencil being used, and this is followed by an application of cold water. The others are treated in the same way on successive days until their complete disappearance takes place.

SALIPYRINE.

In the *Medicinische Revue* Dr. P. Guttmann describes a chemical compound, $C_{18}H_{18}N_2O_4$, which contains in 100 parts 57·7 of antipyrine and 42·3 of salicylic acid, and to this substance he has given the name salipyrine. It is a white crystalline powder, odorless and of slightly acid taste, insoluble in water but soluble in alcohol. Therapeutically, it is an antipyretic and antirrheumatic of considerable value, according to the experiments made by the author.

THE ST. LAWRENCE ASYLUM IN NORTHERN NEW YORK.

A new asylum, known as the St. Lawrence State Hospital for the Insane, was opened on December 1st for the reception of patients. When completed this institution will accommodate 1,500 persons. The New York State Commission in Lunacy is preparing to make a transfer of the pauper insane now lodged in the various almshouses in the northern tier of counties to this new hospital.

A QUINTUPLE BIRTH.

The *Lancet* has an annotation referring to the recent accounts, in the newspapers of Brittany, of the safe delivery of a peasant woman of five children at a birth. She lived at Nozay, near Nantes. At the time of the last report all the children were alive.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 9, 1890:

DISEASES.	Week ending Dec. 2.		Week ending Dec. 9.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus fever	1	0	0	0
Typhoid fever	25	3	19	6
Scarlet fever	93	9	77	6
Cerebro-spinal meningitis	3	3	2	1
Measles	225	12	254	15
Diphtheria	90	28	114	35
Small-pox	1	0	0	0
Varicella	12	0	4	0

The Society of the Alumni of Charity Hospital.—The following-named gentlemen were recently elected officers for the ensuing year: Dr. D. Bryson Delavan, president; Dr. Ramon Guitéras, vice-president; Dr. D. E. Walker, secretary; and Dr. A. T. Muzzy, treasurer.

The Jenkins Medical Association, of Yonkers.—At the next meeting, on Thursday evening, the 18th inst., a report will be presented from the Section in Surgery, and Dr. Joseph D. Bryant, of New York will read a paper.

The Massachusetts Medical Society.—At the meeting of the Section in Clinical Medicine, Pathology, and Hygiene of the Suffolk District Branch, on Wednesday evening, the 17th inst., Dr. W. N. Bullard will read a paper on The Care of Chronic Pauper Epileptics.

The American Public Health Association will hold its eighteenth annual meeting in Charleston, S. C., on Tuesday, Wednesday, Thursday, and Friday, the 16th, 17th, 18th, and 19th inst., under the presidency of Dr. Henry B. Baker, of Lansing, Mich.

Change of Address.—Dr. H. Marion Sims, to No. 4 West Forty-seventh Street.

The late Dr. Richard J. Levis.—At a special meeting of the faculty of the Philadelphia Polyclinic and College for Graduates in Medicine the following preamble and resolutions were unanimously adopted:

Whereas, The Divine Ruler of the universe has seen fit to remove from among us Dr. Richard J. Levis, our friend and colleague; therefore, be it

Resolved, That, in the emeritus professor of surgery of the Philadelphia Polyclinic, not only we, but the whole medical profession, have lost an honored and faithful colaborer; and the community have cause to mourn a skillful and learned physician, an honest and sympathizing friend.

Resolved, That by his kindness of manner, by the thoughtful interest which he always manifested in the younger members of the profession, by his encouragement, his earnestness, and his example, he had endeared himself to all, and that, to fitly honor and cherish his memory, we must emulate his zeal, and vie with each other in carrying forward the great work in which he was engaged.

Resolved, That we tender to his family in this sad hour of affliction our heartfelt sympathy.

Resolved, That these resolutions be handed to the family of our beloved colleague and to the medical journals.

[Signed.] Thomas J. Mays, *President.*
S. Solis-Cohen, *Secretary.*

Society Meetings for the Coming Week:

Monday, *December 15th:* New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otology); Hartford, Conn., City Medical Association; Chicago Medical Society.

Tuesday, *December 16th:* American Public Health Association (first day—Charleston, S. C.); New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings, N. Y.; Ogdensburgh, N. Y., Medical Association; Baltimore Academy of Medicine.

Wednesday, *December 17th:* American Public Health Association (second day); Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medico-legal Society; Medical Societies of the Counties of Allegany (quarterly) and Tompkins (semi-annual—Ithaca), N. Y.; Massachusetts Medical Society, Suffolk District, Section in Clinical Medicine, Pathology, and Hygiene (Boston); Stafford, N. H., District Medical Society (annual—Dover); New Jersey Academy of Medicine (Newark).

Thursday, *December 18th:* American Public Health Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; Metropolitan Medical Society (private); Jenkins Medical Association, Yonkers, N. Y.; New Bedford, Mass., Society for Medical Improvement (private); Addison, Vt., County Medical Society (annual).

Friday, *December 19th:* American Public Health Association (fourth day); New York Academy of Medicine (Section in Orthopædic Surgery); Chicago Gynæcological Society; Baltimore Clinical Society.

Saturday, *December 20th:* Clinical Society of the New York Postgraduate Medical School and Hospital.

Proceedings of Societies.

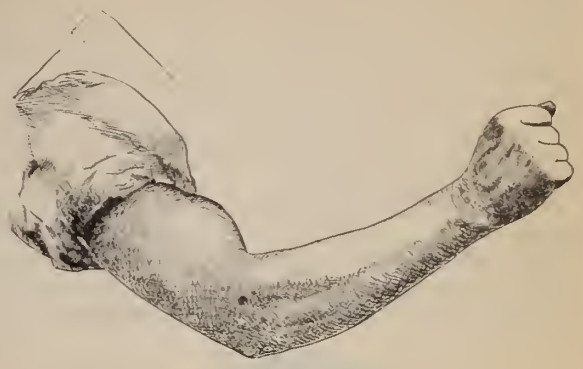
NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Meeting of November 10, 1890.

Dr. Robert Abbe in the Chair.

Rupture of the Short Head of the Biceps.—Dr. V. P. Gibney presented a man of forty years of age who had recently come to the hospital on account of some injury to his knee. The speaker had recognized the patient as one he had treated some seven years ago for rupture of the short head of the biceps muscle. At that time a photograph was taken. No treat-

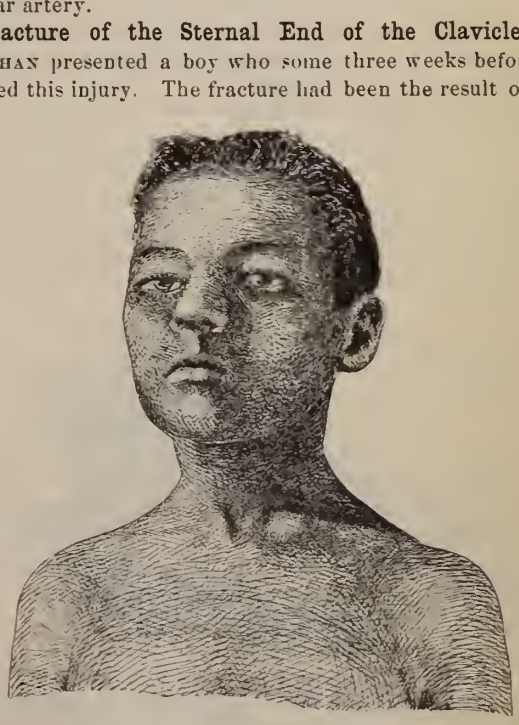


ment was instituted, after consultation with Dr. Bull. The injury had resulted from lifting some heavy body; the man heard a snap and the arm at once fell useless to his side. Some two or three months after the accident the patient had begun to use his arm again a little, and had gradually acquired sufficient power in it to enable him to resume work. He now found it almost as useful as ever, except in certain positions.

Epithelioma of the Nose.—Dr. I. H. Hance showed an elderly woman upon whom he had recently operated for this condition. The epithelioma had followed upon a slight injury to the face, the patient having received a scratch some fourteen years ago which had scabbed over but had never entirely healed. The speaker had done two operations on the face, the primary one consisting in taking a flap from the cheek and turning it over on to the nose. The second operation had included the removal of the scar and the enlargement of the opening into the nostril, use being made of the redundant tissue embraced in the pedicle and flap.

The Chairman thought the result was extremely satisfactory, and the circulation in the flap seemed exceptionally good, which was due, perhaps, to the pedicle being so near to the angular artery.

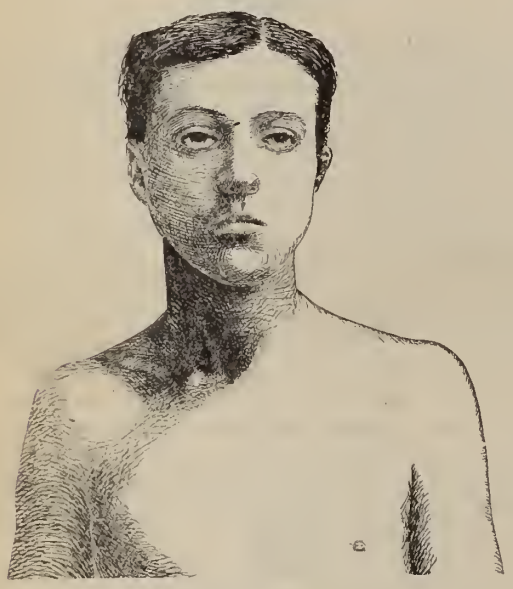
Fracture of the Sternal End of the Clavicle.—Dr. Vaughan presented a boy who some three weeks before had suffered this injury. The fracture had been the result of indi-



rect pressure, some man having leaned his whole weight on the boy's shoulder. There had been but little pain and only slight

swelling following the injury. The fractured sternal end of the clavicle could be felt running up internally to the sterno-cleido-mastoid. The speaker had made every effort to loosen it from its position, but without effect. He had then treated the case by continuous pressure, and the results so far had been satisfactory. The points of interest were the rarity of this form of fracture, the apparent impossibility of reduction at the time of the injury, and the very fair results obtained after only some ten days of continuous pressure.

Dr. C. A. Powers said that he had seen this case soon after the accident. The deformity was extremely marked. He thought that these fractures within an inch of the sternum were rare. He had only come across one among a pretty fair number of collar-bone fractures. The condition in one of these



cases was well shown in the photograph which he exhibited and which was taken a year after the injury. It was difficult to bring these cases out perfect, but he thought that, no matter how great the resulting deformity, the function of the parts involved was generally restored.

Large Tumors of the Neck.—Dr. F. Kammerer exhibited a patient from whom he had removed a large tumor of the neck. His object in bringing the case before the Section was, he said, to suggest the utility of dividing the sterno-cleido-mastoid muscle in removing these large tumors of the lymphatic glands of the neck which included the lower strata of glands below the sterno-mastoid. It was of the very greatest importance to remove all the glandular tissue, and if this were done he thought that the results would be better.

Ankylosis of the Jaw.—The Chairman showed a patient upon whom he had operated some ten years before for ankylosis of the jaw. The results had been happy, immediate, and continuous. When a boy of three years old this patient had had scarlet fever, followed by suppurative otitis and exfoliation of the ossicles. The speaker had cut down, exposing the facial nerve and the carotid artery. The fibers of the nerve were easily held out of the way of injury. He had then cut out a wedge shaped piece of bone at a point about an inch from the articular surface.

The Chairman then showed a girl with the same trouble, who had for fourteen years been unable to open her jaws, her food being pressed into the mouth through the gap left by two absent incisors. The condition had resulted from an injury. There was in this case enough motion to give a clew as to which side the injury had been on. The temporal and masseter muscles showed vigorous contractions, and, though there was a great deal of atrophy of the muscles around the lower jaw, he thought there was every prospect of a good result from operative interference.

Dr. S. T. Armstrong asked if the chairman had any experience with the Italian operation, in which the jaw was divided from within the mouth and motion persisted in, with the idea that this would prevent bony union. He believed that the originator of the operation had recorded several successful cases, but had not heard of any American surgeons taking the operation up.

The Chairman said that the method was that of Rizzoli. It had, however, been superseded by Esmarch's operation, which consisted in removing a segment of the jaw, after external incision, thus insuring a false joint. He thought that resection of the neck of the condyle was a satisfactory procedure. In further answer to a question, the chairman said that the ankylosis found was almost always fibrous. Bony ankylosis was quite rare.

Gonorrhœa in a Boy of Three Years of Age, followed by Tight Urethral Strictures Six Months later, requiring Internal and External Urethrotomy.—The Chairman related the history of this case. The patient, a healthy child, was brought to him suffering with incontinence of urine, pain in the urethra, and a slight discharge resembling gonorrhœa. Nine weeks before, the child had been tampered with by a young woman who had been rescued from the street and given occupation in the house of the child's parents. Within two weeks it had swollen penis, urethritis, incontinence, and pain. It was treated by urethral irrigation with 1-to-8,000 bichloride-of-mercury solution. Gonococci were found in the discharge. Cure had followed in a short time. Six months subsequent to his being sent from the hospital cured, his mother had noticed him in great agony, vainly trying to pass water. He was again brought to the hospital, when his urethra was found strictured and impassable to the smallest instrument. His bladder was aspirated and a pint and a half of urine removed. Aspiration was repeated until the third day, when examination under ether showed three anterior strictures, and one tight one at the membranous portion, which just admitted a filiform bougie. They were dilated gently, but the deep one was so dense that urethrotomy was resorted to. The anterior ones were cut up to No. 22 French with the Otis urethrotome, and the deep one by external perineal urethrotomy. It was found to be a tough, gristly stricture. Perineal drainage by the catheter was continued two days, when a No. 22 sound was readily passed. Four days later, No. 24 was found to slip easily and painlessly into the bladder. After the seventh day all urine had passed *per urethram*. The No. 22 was passed occasionally for several weeks.

Dr. L. B. Bangs said that, although he had seen the disease in very young subjects, he had never seen it in one so young as this. The case was interesting in that it went to show how rapidly the cicatricial tissue following gonorrhœa might be converted into that recognized as stricture tissue. This change had in the present instance taken place in six months. It was also interesting to note the relation between the external measurement of the penis in children and that of the caliber of the urethra. It was surprising to find how easily instruments would enter the normal parts of the canal.

Dr. W. W. Van Arsdale said that he met with a great many cases of what he believed to be gonorrhœa in very young children. He had seen three during the last month. The youngest child was under ten months old. The two others were one year and four years, respectively. These particular cases had not been investigated as to the presence of gonococci, but he believed that the specific proofs would be readily found if

searched for, as they had been frequently demonstrated in similar cases in hospital practice. He met with about ten such cases on an average every year. This was in about the proportion of ten to every three hundred and fifty adults infected. When it was remembered how the parents of many of these children lived, and the way the families were crowded together, the chances of infection would be readily understood as being great. The disease was quite difficult to treat, because of the size of the urethra, and the cases often took two or three months before they could be satisfactorily cured. The diagnosis could be made from the course of the disease. One troublesome feature in the case of young children was that the external parts became eczematous, owing to the accumulation of the discharge, and this led to stricture of the meatus. To avoid this, he now dilated or enlarged the orifice from the first and then tried to persuade the parents to keep the penis open by some moist dressing.

Injuries of the Vertebræ in Children.—Dr. D. J. Woodbury showed two cases of fracture of the vertebræ in young children. The first patient exhibited was a child which had fallen three stories through a fire-escape. When it was brought to the hospital there was a scalp wound exposing the left parietal boss, but no fracture at this point. There was also a hæmatoma in the left parietal region. There was some hæmorrhage from the mouth and nostril. The child was conscious and there were no symptoms of fracture. It was noted that the child, after its admission to the hospital, never could hold its head erect. The chin always rested on the sternum and could not be raised without assistance. No attempt was at this time made to ascertain whether the child could walk or not. A diagnosis of fracture at the base was made, which was, however, changed to that of fracture of the spine. On November 3d the child was brought to the speaker in the out-patient department at Roosevelt Hospital. It could then neither walk nor stand, nor could it sit up without support. The head was thrown forward on the chin and rested on the sternum. The slightest pressure upon the head apparently caused intense pain. There was no constitutional disturbance. On raising the head, by giving support under the chin, it was quite clear that the child was at once relieved. The treatment was with a plaster-of-Paris jacket and jury-mast. The improvement had been marked from the time of the application of the apparatus.

The next patient Dr. Woodbury presented to illustrate another phase of the treatment of these cases. This child had been operated upon soon after being injured. From a study of the treatment of these cases, the speaker was led to the conclusion that operation was generally too long delayed, only being turned to as a last resort. This child had fallen from a bed to the floor, striking upon her back. On admission into the hospital on August 8, 1889, there was incomplete paraplegia. There was loss of sensation and motion in the entire left side and on the right side also, with the exception of slight sensation to irritation in the great toe of that side. There was incontinence of urine and fæces. The disposition was very irritable. There was no high temperature, and emaciation was very great. Dr. McBurney operated, cutting down upon the spinous processes of the third, fourth, and fifth dorsal vertebræ, removing the laminæ with rongeurs and exposing the cord. The dura presented a normal appearance and was not opened. All pressure being thus removed, the wound was closed, a drainage-tube being left in the lower angle. On the fifth day the dressing was removed. Healing had taken place by first intention. The dressings were permanently removed on the fourteenth day. Immediately after the operation the irritability of the child had diminished and the general condition began to improve. The muscles of the back and lower extremities remained in apparently the same condition as before the operation, as did also the bladder and rectum. Faradism was resorted to, but without apparent effect. It was necessary to do something in the way of immobilization, and they had found themselves confronted with the problem as to how properly to adjust a plaster-of-Paris corset to the child, as it was perfectly limp, and under the circumstances the idea of suspension in the usual manner was not to be entertained. The patient was simply an inert mass which had to be carried about upon a pillow. He thought that it would be interesting to show how the difficulty had been surmounted, though he did not claim any originality for the method, as it had already been practiced before. Four layers of common cheese-cloth were obtained, about seven to nine feet long and fourteen inches wide. One end of this was made fast to the wall and the other hitched to a block and tackle so that the tension upon the cheese-cloth could be adjusted. Slits were then cut in the material at about its center, corresponding in position to the arms, legs, and face of the child. The child was then placed face downward upon the cheese-cloth, and its arms and legs were slipped through the slits, the face resting in the slit prepared for it, thus allowing the child to breathe comfortably. It was now only necessary to fix the patient in this position,

which was done by suitable bandaging. The child was now in the best possible position for the satisfactory application of the plaster. In this case a corset was made that would allow of removal for the application of electricity, massage, and other forms of treatment. Within the week there was great improvement in the bladder and rectum, and sensation gradually returned to the lower extremities. The improvement had been continuous, and the patient, as presented to the meeting, was able to stand alone without support of any kind.

Dr. R. H. Sayre said that in all cases where a plaster jacket was applied for the treatment of fractured vertebræ great care was necessary lest more harm than good be done. His father had been in the habit of applying traction to the spinal column as soon as possible, followed by fixation with a plaster-of-Paris bandage. Three of the patients so treated had recovered—two perfectly, and the other to all appearances. This latter patient had stated that he could endure very little fatigue, and that since the injury to his back he had been impotent. The object of applying traction as soon as possible was to endeavor to get

the spine into its normal position and prevent pressure on the cord by the displaced fragments. He thought the method shown by Dr. Woodbury was excellent in every way and could hardly be improved upon.

Dr. Ketch said that in reference to the first case there was

a point which had not been touched upon, and that was the possibility of the existence of Pott's disease in the superior cervical region. Bearing in mind this fact might be of service in doubtful cases. Of course he did not wish to be understood as expressing the opinion that this was such a case. It was found that in disease of the upper cervical vertebræ there was always interference with rotation, and on this a diagnosis could sometimes be made. Where there was interference with flexion, as in this first case, the lesion was lower down—between the second and third or third and fourth vertebræ. It had seemed to him that in this first case the question of fracture was a very doubtful one. He remembered a case in which a child had fallen from a very high place; there was no deformity, and the child did not receive immediate care and died. The post-mortem had shown dislocation of the upper cervical vertebræ. He thought the cases might be treated in an apparatus that gave slight traction and support to the head in a proper direction. He had noticed that the patient with the jury-mast was allowed to turn its head. He thought the head should be immobilized with a certain amount of traction. The question of diagnosticating locality in these cases was very obscure, and if some deductions could be made from cases of Pott's disease, he thought this was a valuable point.

Dr. Woodbury said that rotation was now perfectly painless to the child. Before it was treated with this support motion had been impossible.

SECTION IN PÆDIATRICS.

Meeting of November 13, 1890.

Dr. L. Emmett Holt in the Chair.

Practical Hints on Sterilizing Milk.—Dr. Walter Mendelson read a paper with this title. He said that much of the confusion and dissatisfaction of the laity in preparing sterilized milk was due to the fact that the theoretical principles upon which they must work had never been simply and fully explained to them. He thought that it was not only the physician's duty to let the one upon whom the preparation devolved know the means, but the object as well. Explain to her or him that investigation had shown that not only were the curdling, souring, and other obvious changes due to the growth of bacteria or minute germs in the milk, but also that various dyspeptic and diarrhœal diseases of bottle-fed children were caused by the presence in the milk of similar minute organisms which might produce no change in the milk itself. Tell them that it had been found that, when milk had been heated to the boiling point and kept there for some time, both the plants and their seeds were killed and the milk was thus rendered fit for food. After having explained that the object was to prepare a food free from germs, the next thing was to show how to accomplish this. The milk, or suitable mixture of milk, water, cream, and sugar, should be prepared as early in the morning as possible, before the heat of the day had caused the bacteria to multiply. Great care must be taken in cleansing the bottles and nipples, and for this purpose "pearline" seemed to answer the best, using it with hot water and a bottle brush. The same bottle should never be used the second time without washing. With regard to stoppers, the best consisted of a plug made of ordinary cotton batting, folded into a pretty firm wad, and pushed down for half an inch or more into the neck of the bottle. The nipple should be a plain conical, pure gum one, with no constrictions in it, so that it could readily be turned inside out for cleansing. When not in use it should be scrubbed clean and placed in a glass of water to which a teaspoonful of borax had been added. As for the sterilizer, any apparatus would do that would answer the purpose of keeping the milk for about an hour at the temperature of boiling. But of the specially devised affairs for this purpose, "Arnold's steam sterilizer" was the most ingenious and at the same time simple. The sterilizing of milk had marked a great advance in our methods of infant feeding, and, as the triumphs of medicine in the future would seem to lie in the direction of preventing illness rather than of curing it, it should be the pride and interest of every physician to popularize the method under discussion, for it had already done much to lessen the morbility and mortality among infants.

Results of the Use of Sterilized Milk.—Dr. H. Koplik read a paper giving the results of his treatment with the sterilized milk in one hundred and thirty-four dispensary patients. (To be published.)

A member from Brooklyn said that they had now perfected all the arrangements in that city by which one of the large dairies did the work of thoroughly sterilizing a quantity of milk daily, putting it up in properly constructed bottles for delivery at the residences of customers. One of the preparations contained a proportion of cream. As to the legality of putting this upon the market in such form there had been some dispute, but quite recently a legal opinion had been given which practically settled the question, and there was now no reason why this and other preparations of sterilized milk should not be in general use.

Peritonitis in Infancy and Childhood.—This was the title of a paper by Dr. J. Lewis Smith. He said that peritonitis was likely to occur at any age, but the most interesting and fatal form was that which occurred in the newly born. This form had in times past been quite common in maternity wards and in tenement houses, in degraded and filthy families, who had no knowledge or thought of sanitary requirements. There was no doubt that in the ætiology of peritonitis in the newly born microbes played a most important part. The septic matter no doubt entered the system through the umbilicus, usually from the use of foul dressings, foul water employed in washing, foul fingers of the nurse, or other sources. Umbilical inflammation, with perhaps ulceration and the formation of a phlegmon, might occur, and septic matter be taken up by the umbilical lymphatics or blood-vessels and carried into the system. Peritonitis occurred in infancy and childhood from a variety of causes. It sometimes resulted from extension of inflammation from the abdominal walls or from one of the viscera which was the seat of a tumor or adventitious growth, encroaching upon and irritating the peritonæum. Septic infection occasionally caused peritonitis, when the conditions were favorable for it, in older children as well as in the newly born. Chronic degenerative disease of the kidneys was also a recognized cause of peritonitis, but less frequently in children than in adults. It was now known that a considerable number of the diseases which were formerly supposed to be due to taking cold were caused by microbes. Perhaps there was too great a tendency at the present time to ignore thermal changes in the atmosphere or exposure to cold as a cause of disease. In ill-nourished and scrofulous children inflammation and cheesy degeneration of the mesenteric glands sometimes gave rise to inflammation in the portion of the peritonæum which covered them. But peritonitis in infancy and childhood more frequently resulted from disease of the hollow organs than from that of the solid viscera. Intussusception, attended by bloody stools, tenesmus, vomiting, abdominal tenderness, and the occurrence of an abdominal tumor, was more common in infancy after the age of six months than in any other period of life. Another not infrequent cause was appendicitis due to the lodgment of a foreign substance in the appendix, or of a concretion, which caused by its presence pressure inflammation, ulceration, and

finally perforation. Children less frequently than adults had ulceration of Peyer's patches in typhoid fever, but it sometimes occurred, ending in perforation or rupture and fatal peritonitis. Peritonitis had been known to follow traumatism of the abdomen. Recently a considerable number of cases had been published showing the microbic origin of peritonitis in certain instances. Some of the cases were caused by accidental inoculation, and others were due to the inhalation of sewer-gas. Experiments had been made, designed to elucidate the causal relation of microbes to peritonitis. Prince had found that the injection into the abdominal cavity of a small amount of an irritant not containing microbes—such as mineral acid, phenol, and nitrate of silver—caused peritonitis, but it was always serofibrinous, never purulent. Grawitz, in his experiments, had shown that, as a rule, two things were necessary for the causation of purulent peritonitis—to wit, the introduction into the peritoneal cavity of pus-producing organisms, and an abnormal state of the peritonæum from injury or contagious disease. Another observer had shown that if the peritonæum was in its normal state it might absorb a considerable amount of septic matter with no serious result, but that if it was injured or the subperitoneal connective tissue was exposed to infection, purulent peritonitis was likely to result. Experiments thus far had not perhaps been very satisfactory in throwing light on the microbic origin of peritonitis, but they seemed to show that purulent peritonitis, as a rule, resulted from the action of microbes, and the microbes known to be pathogenic caused peritonitis when injected into the peritoneal cavity, while the non-pathogenic germs did not produce such a result, even in a lesser degree. Tubercular peritonitis occurred much more frequently in infancy and childhood than in adult life. The symptoms, when peritonitis was due to a pre-existing disease, were, of course, accompanied by the symptoms of that disease, by which it might be rendered more or less obscure. The symptoms might begin in any manner, with gradually increasing tenderness of the abdomen, or abruptly with a chill or rigor. Constant pain increased by movements of the body or by pressure was the distinctive symptom occurring in localized peritonitis at the seat of the inflammation, but in diffuse peritonitis it began at some point and gradually extended over the abdomen. Tenderness on pressure was seldom absent, and the pain intensified by coughing or a full inspiration was in most cases seen in the early stage of the disease. The extension of the inflammation over the intestines produced paralysis of their muscular layer so that they became distended with gas. In cases of great abdominal distention the apex of the heart was carried upward, the liver and spleen were pressed upward and backward, and the distended transverse colon or portions of the duodenum or jejunum might lie in front of them, so that the normal dullness on percussion over these organs was replaced by the tympanitic resonance. The percussion-sound over the effused liquid was, of course, dull. The patient was quiet on account of the pain, lying upon the back or side with the knees flexed to relieve the tension, but the position was not uniform, as the legs might even be found extended. Constipation was usually present in the early stage. Vomiting was a common and painful symptom. The pulse was accelerated in some cases, very frequent as well as very feeble. The countenance was anxious, but the mind was clear, or there might be a mild delirium, the speech being incoherent and rambling. Retention of urine was common. In the pathological anatomy of localized peritonitis the action of the cause, as the name implied, was limited to a portion of the peritonæum. In acute diffuse or general peritonitis the inflammation commonly began at one point, but it rapidly extended over the peritonæum. The relative proportion of the different inflammatory products varied greatly in different cases, and in all not only were serum and fibrin present, but pus-corpuscles could be detected under the microscope. The fibrinous exudation upon the peritoneal surface occurred either in patches or continuously over a considerable part of the visceral peritonæum. It was prone to form a covering of varying thickness over the large and immovable organs. The connective tissue underlying the peritonæum underwent proliferation, producing granulations, which, when coming in contact with opposing surfaces, united, forming adhesions, and these at times involved the intestines and viscera, producing disastrous results. In purulent peritonitis, the pus formed, being heavier than the serum, gravitated to the lowest part of the abdominal cavity. In patients that recovered the serum was the first to be absorbed, and the fibrin and pus cells underwent fatty degeneration, became granular, liquefied, and were absorbed. Sometimes collections of pus became encapsulated and remained inert. By careful attention to the distinctive symptoms a mistake in diagnosis ought not to occur. Peritonitis in children was always a grave disease; in most instances its progress was rapid toward a fatal termination. The author was confident that much could be done in the way of prophylaxis in these cases if a little more attention was given to the matter. Scarcely any disease more urgently required early and judicious treatment than the one under consideration. Proper selection of the diet was a matter of the greatest importance. Such food should be recommended as was most concentrated, predigested, or easy of digestion, and such as would give the minimum amount of fæcal matter. Sterilized milk was by far the best food for this purpose. For children over two years of age some farinaceous food could be added. Purgatives should be avoided. A nutritive or laxative enema was the best for this purpose. Of the drugs, opium, camphor, digitalis, alcohol, and strophanthus were used, as the urgencies of individual cases required. The removal of the cause of a disease, if it could be effected safely without material injury to the patient, evidently contributed greatly to recovery.

The Chairman said that a great deal of stress had been laid from time to time upon the grape-seed point. He had never yet found such seeds in any appendix vermiformis. He thought it was a little hard on children that, on the strength of this apprehension, they were to be debarred from eating fruit.

Dr. J. E. Winters thought that the most important causes of peritonitis in children were typhlitis, perityphlitis, appendicitis, traumatism, tuberculous disease, and intussusception. In regard to the first three conditions, the cases, of course, required to be seen early, when he thought that a critical examination ought to result in a correct diagnosis. The traumatic cases were more difficult, for the reason that most children were unwilling to acknowledge the indiscretion which had led up to the traumatism. In dispensary practice this was particularly difficult to elicit; but brutal treatment by the parents was a frequent cause of the peritonitis. The tubercular variety required acquaintance with the family history, and called for a thorough examination as to the existence of general tubercular disease in the patient. Without all these points, few physicians would be willing to make a diagnosis of tubercular disease in the peritoneal cavity. In intussusception the symptoms were sufficiently pronounced to make a diagnosis tolerably easy. A diagnosis of peritonitis from either of the three first-named causes having been made, then came the question of management. He thought that at the present time most men used cold. The inflammatory processes were sufficiently superficial to be influenced by the external application of cold, and he thought that the results were, on the whole, more favorable than from heat. Only in the case of absolute inability on the part of the patient to tolerate its application would he use anything for external

application except ice. If cold would not relieve the pain, then morphine must be used. It was important to remove all substances from the large intestines, and for this purpose he thought that it was best to employ small doses of triturated calomel.

The frequent injection of ice-cold water into the rectum was desirable after the use of the calomel, or of castor-oil. In the traumatic cases, having gained the confidence of the child and obtained a careful history of the case, he thought that cold applications and a clearing out of the alimentary canal were, as a rule, sufficient, together with the strictest dietetic management. In the tuberculous cases the physician could endeavor to give relief by counter-irritation by means of iodine. In this way the early indications might be met. If suppuration was expected, an operation might be resorted to. In cases of perityphlitis and appendicitis, where, having made a causal diagnosis, and having failed by judicious means to relieve the local symptoms, laparotomy should be suggested. As now undertaken, the operation was not serious, and it was far simpler at the outset than after extensive adhesions and infiltration had taken place.

Dr. Smith thought that, if the surgeons were to examine the concretions carefully which they found in the appendices, they would often discover that seeds and other foreign bodies were the real cause of the trouble. He was not inclined to withdraw from the stand he had taken in the matter of grape seeds.

SECTION IN THEORY AND PRACTICE OF MEDICINE.

Meeting of November 18, 1890.

Dr. Francis Delafield in the Chair.

The Medical Aspect of Trephining in Epilepsy.—Dr. J. C. Minor read a paper with this title. He said that, from long clinical observation, he had concluded that epilepsy did not disappear spontaneously, but that about one half of all the cases presented for treatment were curable, whether the cases called for medical or for surgical treatment. The reason that surgical interference did not offer better results was, the speaker thought, due to the cases not having been properly selected. He thought that the indications for trephining in epilepsy were pretty definitely marked out. The indications were described under three headings: 1. Those that were plainly traumatic and presented a depressed fracture of the skull, osteitis, and tumors of the brain. 2. Those without any apparent lesion of the skull, but with old cicatrices of the scalp. 3. All those cases of epilepsy the symptoms of which indicated cortical lesions. The speaker was satisfied that more than half the cases presenting for treatment would come under one of the above groups. The history of a case was then reported. The patient, a young man, seventeen years of age, had five years ago been hit on the head with a brick which had fallen from quite a height, producing only a scalp wound. Four years later the first attack came on, and during the last year epilepsy had become fully established. The attacks came on with a distinct aura, contractions commencing in the right hand and arm. Pressure on the scar would bring on the aura and produce a typical attack. Trephining in this case had disclosed no injury to the skull, but the removal of the cicatrix had ameliorated the condition. The speaker, from his observations in this case, was led to the conclusion that it was always well to begin the treatment, in cases presenting cicatrices, by removing the scar. Several cases had been reported cured, treated in this manner, and he thought it was well worth trial. He did not think that in trephining at the site of injury the actual lesion caused by it could be found in every case. The contra-indications for operative interference were in all those cases where the cause was not clearly defined and in those of long standing where the patient's mind had become enfeebled and the general condition would offer no hope of recovery. Finally, when the indications were for surgical treatment, the operation should be done promptly, as by so doing the best possible chance would be given to the patient.

Dr. Robert F. Weir was quite in accord with the rules laid down by the speaker. Despite the fact that operations were being done on the brain by some of the most careful surgeons, the mortality was still quite high, averaging from fifteen to twenty per cent. His experience in brain surgery had led to the conclusion that much would yet be done in this direction, but that when the technique of the operation was better understood the results would be better.

Dr. Robert Abbe reported the histories of two cases in which an operation had been performed, the results of which led to the conclusion that conservatism was to be practiced in operating in such cases.

Dr. E. D. Fisher thought that it was a difficult matter to say which cases should be operated on and which not. He thought that chronic epilepsy, traumatic lesions with consequent organic lesion, congenital spastic paraplegias with associated epilepsy, and a focal lesion becoming general, were certainly not suitable for operation. Cases had been met with where the scar was a source of irritation, but again it was often present when it did not cause any trouble whatever, so he could not agree with the speaker in thinking that it was a good thing to trepbine in these cases. He had had a case which had appeared to offer every indication for trephining. The operation had seemed to be a success, the patient had improved for two or three weeks, but had after that relapsed into his old condition. It was the speaker's opinion that all the cases of idiopathic type of epilepsy were originally traumatic.

Dr. L. C. Gray thought that, in reviewing the question of the indication for operation in epilepsy, it would be just as well to first ask what was epilepsy. It was still a question as to whether epilepsy was a disease or a symptom of one, and if either, what were the cause and nature of it? Whether it might not be due to peripheral irritation had been pretty thoroughly gone into, and it was found that after every source of irritation had been removed the attacks went on the same as before. The histories and data were wanting in definite value. This was thought to be due to the fact that cases were not kept under observation long enough, and not followed up with a definite object. Idiopathic epilepsy with marked changes had been known to go on for years without a fit having occurred. There was no doubt that many of the cases were organic in origin. Those that were due to meningitis in early infancy certainly could not be operated upon. Such cases as were due to the same causes were called in the adult idiopathic, simply because the definite course of the disease was not known. The traumatic cases offered but little better results for operative interference on account of the very limited knowledge of the focal centers. The only ones isolated were those of the arm, leg, speech, word-deafness, and hæmianopsia; when we undertook to go beyond that point we were in the field of speculation. It was still a question whether, if operation were performed in cortical epilepsy, the habit of the explosion was not too confirmed to cease. The speaker related the history of a case of subcortical lesion in which no loss of consciousness had occurred. He thought the whole question bearing on epilepsy was still distinctly *sub judice*.

Dr. Minor said that the indications and rules laid down by him had been made up principally from reports and his own clinical experience. He was sure that some cases had been

cured of the attacks by the operation, but he was also of the opinion, as Dr. Gray had expressed it, that the habit could not be easily broken up and that it was likely to return. In operating in cases of idiopathic epilepsy where no scar could be found he had never known it to do the patients harm. The operation in these cases was done on the principle of cerebral pressure. He had recently seen an old patient upon whom he had operated some twenty years ago, removing a large portion of the frontal bone with a quantity of brain tissue. It was interesting to know that there had never been any development of epilepsy, but the mental and moral degradation was complete.

Book Notices.

Diseases of the Eye. By Edward Nettleship, F. R. C. S., Ophthalmic Surgeon to St. Thomas's Hospital, etc. Fourth American from the Fifth English Edition. With a Chapter on Examination for Color-perception, by William Thomson, M. D., Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. Philadelphia: Lea Brothers & Co., 1890. [Price, $2.]

This is a well-known and a valuable work. It was primarily intended for the use of students, and supplies their needs admirably, but it is far from being a mere quiz compend. On the contrary, it is as useful for the practitioner, or indeed more so. It does not presuppose the large amount of recondite knowledge to be present which seems to be assumed in some of our larger works, is not tedious from over-conciseness, and yet covers the more important parts of clinical ophthalmology.

A supplement is made to the present edition on the practical examination of railway employees as to color-blindness and acuteness of vision and hearing. This is well written, and contains good suggestions for those who may be called upon to make such examinations.

BOOKS AND PAMPHLETS RECEIVED.

Les microbes de la bouche. Par le Dr. Th. David, Directeur de l'école deutaire; chirurgien dentiste des Hôpitaux de Paris. Precédé d'une lettre-préface de M. L. Pasteur. Avec 113 figures en noir et en couleurs dans le texte. Paris: Félix Alcan, 1890. Pp. xv–302.

Memorial Sketches of Dr. Moses Gunn. By his Wife. With Extracts from his Letters and Eulogistic Tributes from his Colleagues and Friends. Chicago: W. T. Keener, 1890. Pp. xx–380.

Household Hygiene. By Mary Taylor Bissell, M. D. New York: N. D. C. Hodges, 1890. Pp. 83. [Fact and Theory Papers.]

A Manual of Weights and Measures. Including Principles of Metrology; the Weights and Measures now in Use; Weight and Volume and their Reciprocal Relations; Weighing and Measuring; Balances (Scales) and Weights; Measures of Capacity; Specific Weight and Specific Volume, etc. With Rules and Tables. By Oscar Oldberg, Pharm. D., etc. Third Edition, revised. Chicago: W. T. Keener, 1890. Pp. vi–250.

A Clinical Study of Diseases of the Kidneys, including Systematic Chemical Examination of Urine for Clinical Purposes, Systematic Microscopical Examination of Urinary Sediments, Systematic Application of Urinary Analysis to Diagnosis and Prognosis; Treatment. By Clifford Mitchell, A. M., M. D. Chicago: W. T. Keener, 1890. Pp. xii–431.

A Laboratory Manual of Chemistry, Medical and Pharmaceutical, containing Experiments and Practical Lessons in Inorganic Synthetical Work; Formulæ for over Three Hundred Preparations, with Explanatory Notes; Examples in Quantitative Determinations and the Valuation of Drugs; and Short Systematic Courses in Qualitative Analysis and in the Examination of Urine. By Oscar Oldberg, Pharm. D., etc., and John H. Long, Sc. D., etc. With Original Illustrations. Second Edition, revised and enlarged. Chicago: W. T. Keener, 1890. Pp. 3 to 457.

The Patients' Record, for the Use of Physicians and Nurses. Compiled by Agnes S. Brennan. New York: G. P. Putnam's Sons, 1890. [Price, $2.]

Lectures at St. Peter's (in 1890) on Some Urinary Disorders connected with the Bladder, Prostate, and Urethra. By Reginald Harrison, F. R. C. S., etc. London: Baillière, Tindall, & Cox, 1890. Pp. 5 to 81.

Differentiation in Rheumatic Diseases (so called). (Read before the Bristol Medico-chirurgical Association, 14th of May, 1890.) By Hugh Lane, L. R. C. P., etc. [Reprinted from the *Lancet.*]

The Time-relations of Mental Phenomena. By Joseph Jastrow, Professor of Psychology at the University of Wisconsin. New York: N. D. C. Hodges, 1890. Pp. 60. [Fact and Theory Papers.]

Chloroform and the Hyderabad Commission. The President's Address delivered at the Annual Meeting of the Southwestern State Medical Society of Ohio, Cincinnati, October 16, 1890. By J. C. Reeve, M. D., Dayton. [Reprinted from the *Medical News.*]

Report on Surgery. By W. L. Rodman, M. D., Louisville. [Reprinted from the *American Practitioner and News.*]

The Sensation of Itching. By Edward Bennet Bronson, M. D. [Reprinted from the *Medical Record.*]

The Rotary Element in Lateral Curvature of the Spine. By A. B. Judson, M. D. [Reprinted from the *Medical Record.*]

The Relation of Bacteria to Practical Surgery. The Address in Surgery delivered before the Medical Society of the State of Pennsylvania, June 4, 1890. By John B. Roberts, A. M., M. D.

Report of Three Hundred Cases of Intubation of the Larynx. By F. E. Waxham, M. D. [Reprinted from the *North American Practitioner.*]

Treatment of Scarlet Fever and its Complications. By J. Henry Fruitnight, A. M., M. D., New York. [Reprinted from the *Archives of Pædiatrics.*]

Report of Two Cases of Uterine Fibroid and One of Stricture of the Rectum, treated by Electrolysis and Surgically. Also Presentation of Specimen of Dermoid Cyst. By J. B. Greene, M. D., Mishawaka, Ind. (Read before the Chicago Medical Society.)

A Regional Study of Tumors. By W. L. Rodman, M. D., Louisville. [Reprinted from the *American Practitioner and News.*]

Rotura espontanea de la matriz al cuarto mes de gestación. Por el Doctor Eduardo F. Pla. [Publicado en la *Crónica Medico-quirúrgica de la Habana.*]

Seventeenth Annual Report of the Maternity Hospital, Philadelphia.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Semi-annual Session, held at Hagerstown, Md., November, 1889. Ninety-second Annual Session, held at Baltimore, Md., April, 1890.

Report of the Board of Trustees of the Eastern Michigan Asylum, at Pontiac, for the Bieunial Period ending June 30, 1890.

Twenty-first Annual Report of the State Board of Health of Massachusetts.

Lehrbuch der allgemeinen und speciellen pathologischen Anatomie für Aerzte und Studirende. Von Dr. Ernst Ziegler, Professor der pathologischen Anatomie und der allgemeinen Pathologie au der Universität Freiburg in Baden. Zwei Bände. Sechste neu bearbeitete Auflage. Zweiter Band. Specielle pathologische Anatomie. Mit 435 theils schwarzen, theils farbigen Abbildungen. Jena: Gustav Fischer, 1890. Pp. xii–3 to 1024. [Preis, Mrk. 16.]

Rumination in Man. By Max Einhorn, M. D., New York. [Reprinted from the *Medical Record.*]

A New Method of obtaining Small Quantities of Stomach Contents for Diagnostic Purposes. By Max Einhorn, M. D., New York. [Reprinted from the *Medical Record.*]

One Hundred Consecutive Cases of Labor at the Maryland Maternity. With a Description of the Methods practiced in that Institution. By George H. Rohé, M. D., Director, and W. J. Todd, M. D., Resident

Physician. [Reprinted from the *Transactions of the Medical and Chirurgical Faculty of the State of Maryland.*]

The Early Operation for Hare-lip, with the Report of a Case, Illustrations, etc. By Thomas H. Manley, A. M., M. D. [Reprinted from the *Medical Age.*]

Amputation of Roots as a Radical Cure in Chronic Alveolar Abscess; in Pyorrhœa Alveolaris complicated by Alveolar Abscess. By M. L. Rhein, M. D., D. D. S., New York. [Reprinted from the *Proceedings of the American Dental Association.*]

Two Cases of Fractured Skull. Recovery in One; Death from Chloroform in the Other. By Thomas H. Manley, M. D., New York. [Reprinted from the *Medical News.*]

Rupture of an Ectopic Sac in the Sixth Month of Pregnancy. Abdominal Section and Recovery. By Dr. James Moran and Dr. T. H. Manley, New York.

The Treatment of Contracted Bladder by Hot-water Dilatation. By I. S. Stone, M. D., Washington, D. C. [Reprinted from the *Transactions of the Southern Surgical and Gynæcological Association.*]

The Diagnosis of Pelvic Disease, or when to operate. By I. S. Stone, M. D., Washington, D. C. [Reprinted from *Practice.*]

Some Considerations in regard to Acute Obstructive Diseases of the Lungs. By Andrew H. Smith, A. M., M. D., New York. [Reprinted from the *American Journal of the Medical Sciences.*]

Fourth Annual Report of the Training School for Nurses connected with the Post-graduate Medical School and Hospital, May 31, 1890.

Medical Missionaries in Relation to the Medical Profession. Read at the Meeting of the China Medical Missionary Association, held at Shanghai, May 19–22, 1890. By J. G. Kerr, M. D., Canton, China.

Miscellany.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for December 5th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.....	Nov. 29.	1,651,798	654	..	..	..	..	..	..	..	..	..	..	....
Chicago, Ill.....	Nov. 29.	1,100,000	323	..	..	..	..	..	..	16	4	23	1	6

Observation of Koch's Treatment of Tuberculosis.—In accordance with a resolution of the Dauphin County (Pa.) Medical Society, Dr. E. H. Coover, Dr. Hugh Hamilton, and Dr. Thomas J. Dunott have been appointed a committee to visit Philadelphia, at the proper time, and inspect the method of employing Koch's remedy for tuberculosis as used in the hospitals there.

Syphilitic Infection from a Bite.—"A patient was recently shown to the Berlin Medical Society who was said to have contracted syphilis from the bite of a man. The bite was inflicted on the lip, and the wound healed in two or three days, but in six weeks it reopened and the lip became greatly swollen. Five weeks later there was an ulcer on the inner surface of the lip with great swelling and induration round about; the submaxillary and cervical glands were also much enlarged. After some time a typical syphilitic eruption made its appearance. By the use of mercurial frictions the swelling both of the lips and of the glands was considerably reduced."—*British Medical Journal.*

ANSWERS TO CORRESPONDENTS.

No. 337.—Approval of the diploma by the Board of Regents of the University of the State of New York, and subsequent registration of it at the County Clerk's office.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

COMPLETE AND PERMANENT RECOVERY BY JEJUNO-ILEOSTOMY WITH SENN'S BONE PLATES IN INTESTINAL OBSTRUCTION DUE TO INTUSSUSCEPTION AND SLOUGHING OF THE INTUSSUSCEPTUM.

BY THOMAS H. RUSSELL, M. D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, YALE UNIVERSITY, AND SURGEON TO THE CONNECTICUT STATE HOSPITAL.

ON August 16, 1889, I was summoned to visit a boy, fifteen years of age, living on a farm in Montville, Conn. I found that he was suffering from very severe chronic obstruction (stenosis) of the small intestine.

The history of the case was as follows:

Until October 2, 1888, he had been strong and in perfect health, but on that day, while wrestling, was attacked by an extremely acute pain in his abdomen, quickly followed by severe vomiting and obstinate constipation, which persisted for five days. On the fifth or sixth day his bowels were moved, and the vomiting became less severe. During the next few weeks the emesis was less frequent, the pain became intermittent, although severe, and the constipation gradually changed to diarrhœa.

On November 1st (or soon after) a soft, fleshy mass was noticed in one of his stools.

During the ten months preceding my visit and operation he had been under the care of Dr. Smith and Dr. Bishop, of Norwich, Dr. Matthewson, of Montville, and others.

During these ten months he was confined to bed much of the time, and there were occasional attacks of vomiting and from three to seven light-colored liquid stools daily, but free from blood. The abdomen was much distended and tympanitic; his appetite was poor and his tongue coated.

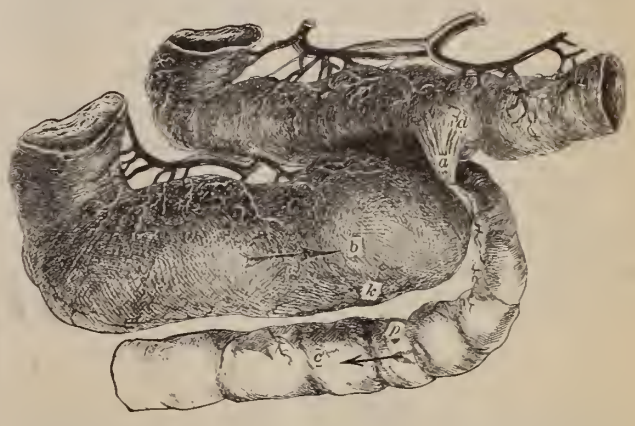
He became much emaciated and had night sweats, but no elevation of temperature. During these ten months he suffered from severe attacks of abdominal pain, recurring about every twenty to forty minutes night and day, and lasting from three to five minutes. Each of these attacks of pain was preceded or accompanied by such violent intestinal peristalsis that the contour of the intestine formed very prominent visible ridges in the abdominal wall.

In each attack the severe pain commenced after the violent peristalsis had lasted one or two minutes, and disappeared suddenly when, three to five minutes later, there was a loud sound as of gas and liquid being forced through a small orifice. Immediately afterward the pain and peristalsis would cease, and the patient become comfortable.

The pain was sometimes above the umbilicus and at other times below or to the right or left, and not confined to any one point. All his symptoms were gradually becoming more severe. During my visit on August 16, 1889, I was able to observe a number of these attacks, and it appeared probable (as the laparotomy next day proved true) that they were due to nearly complete obstruction in the small intestine. The regularly recurring, violent, and painful peristalsis was the effort of the intestine to force its contents through a very small aperture. Laparotomy being indicated, I operated on the following day (August 17, 1889), assisted by Dr. Smith, of Norwich, Dr. Matthewson, of Montville, and Dr. R. S. Bradley, of New Haven.

The incision extended from the umbilicus to the pubes. I found it impossible to locate the obstruction without removing the small intestines from the abdomen, and, while doing so, protected them with napkins wrung out of hot Thiersch's solution. The obstruction was found at a point near the junction of the upper and middle thirds of the small intestine.

As shown in the accompanying illustration, the small intestine, *b* to *c*, was so extremely contracted at *a* that its diameter was only about a quarter of an inch, and at that point it was firmly bound down by a strong old band of adhesion, *a*, to the wall of an adjacent loop of intestine, *d*.



All of the portion of intestine *b* above the obstruction *a* was distended to about three times its normal caliber and filled with gas and liquid fæces. All of the portion of intestine *c* below the obstruction was empty, contracted, and flaccid.

The obstruction was evidently an old one, and it was plainly impossible to restore the caliber of the bowel at that point. The best plan was evidently to establish an intestinal anastomosis, as suggested by Professor Senn. After locating the obstruction, it was found impossible to return the rest of the intestine into the abdomen, owing to its distention above the obstruction.

I therefore made a linear incision, an inch and a half long, at *k* above the obstruction, and emptied all of the contents of the bowel, consisting of about a quart of yellow liquid fæces and a large amount of gas, into a pan. The intestine was then easily replaced within the abdomen. A Senn's perforated decalcified-bone plate was then introduced through the incision in the bowel at *k*, and another bone plate was introduced below the obstruction through an incision at *p*. The bone plates were approximated after scarifying the serous surfaces, and about twelve Lembert sutures were introduced around the circumference of the plates. The intestine was then cleansed and the abdomen flushed with hot Thiersch's solution, and the abdomen closed.

His recovery was rapid, perfect, and permanent. Although his temperature was taken every two to four hours for eight days, it only once went above normal, and then only transiently touched 100·2° on the second day. I did not visit him after the sixth day, the nurse was discharged on the eighth, the patient sat up about the tenth, and was down stairs about the sixteenth or eighteenth day. Dr. Smith made a few visits afterward. The patient had a large normal stool five days after the operation, and his bowels moved regularly afterward. All stools were examined for traces of the bone plates. Nine days after the operation the remains of a bone plate (probably the distal one) were found in one of the stools. It was of only about a quarter of the thickness, half of the width, and two thirds of the length of the original plate, and was so soft as to require careful handling. A few days later, barely perceptible remnants of the other plate were evacuated, and none subsequently. From that time he quickly and steadily improved in health in every respect, and resumed his work

on the farm. It is now *fifteen months* since the operation, and he is in every way enjoying good health.

The boy is strong and able to do ordinary work. There is every indication that his recovery is absolutely complete and permanent. I believe that this is the most successful case of the kind thus far on record. It seems evident that the commencement of his disease on October 2, 1888, was an intussusception (at point A in the diagram), that the soft, fleshy mass passed in one of his stools about a month later was the intussusceptum, which had sloughed out, and that the subsequent stenosis and adhesions were results of that process.

My experience in this case and in another, in which I performed gastro-enterostomy with decalcified-bone plates for cancerous stenosis of the pylorus, convinces me that the bone plates are much to be preferred to the various catgut substitutes (rings and mats) and all other substitutes which have been suggested. They are admirably adapted for the purpose and need no improvement.

REPORT OF A CASE OF INTESTINAL ANASTOMOSIS FOR FÆCAL FISTULA,

*WITH REMARKS.**

By CHARLES H. RICHMOND, M. D.,
LIVONIA, N. Y.

On the 1st of January, 1890, I was called to see W. W. R., of Honeoye, N. Y., in consultation with Dr. Green and Dr. Wilbur. The patient was forty-six or forty-seven years old, of slight build, considerably emaciated, showed spells of elevated temperature, and had enlargement of some of the glands of the right groin, with tenderness of the adjacent muscles. Rectal examination elicited no pelvic bunches. The patient had recently recovered from an attack of peritonitis and was still in bed part of the time. Some ten or twelve years ago he had peritonitis, followed by venous thrombosis of the right limb, or phlegmasia alba dolens. He has had more or less trouble with the limb since.

About the 1st of June last, six months after my visit, Mr. R. called at my office in Livonia on his way to Rochester to consult an eminent practitioner. He was markedly thin and anæmic, complained of lameness and distress in the right iliac region, increased by pressure on the back, and had a temperature of 100°. The diagnosis seemed to rest between disease of the appendix and psoas abscess, with the probabilities, in view of the history of the case, of the former. At that time I advised an exploratory incision with the object of removal of the appendix if found diseased, or the evacuation of an abscess if already existing; but, there being no concurrence of opinion, simple measures only were resorted to.

During the latter part of July an increase in the tenderness of the parts about the groin and hip joint, with elevation of temperature, took place, and on the 8th of August, in the presence of Dr. Wilbur and Dr. Green, I opened an abscess which had become manifest on the right thigh, a little below the hip joint and on the outer aspect of the limb. It contained pus, gas, and fæcal matter, the odor of which was the very prince of stinks. The nature of the trouble was now positively known, but, the patient's condition being bad, it was thought best to delay further operative procedure until he might recuperate and at the same time be allowed time for the possibility of spontaneous closure of the fistula.

A fæcal fistula occurring at the head of the colon is much more disagreeable and debilitating than an artificial anus at the sigmoid flexure, for the contents of the gut are thinner, causing a more constant discharge with consequent local irritation, and the tract of the fistula, with its pus-secreting walls, is a source of debility and septicæmia.

I saw the patient two or three times within the following three weeks, during which time fæcal matter continued to pour out of the orifice of the abscess in abundance, a smaller portion passing *per rectum*, the patient's condition meanwhile growing no better, except in a fall of temperature to nearly the normal point since the opening of the abscess. I then began to think seriously of an abdominal operation. After giving the matter some thought and laying the case before some medical men, among whom was Dr. G. H. Bosley, of New York, I communicated with Dr. Wilbur, suggesting the propriety of some procedure. In the mean time Dr. Frank Becker, of New York, had seen the patient and advised an operation, but I do not know upon what plan. The family, after a time, felt that the only hope for life was in having the fistula closed, and the patient preferred death to an open fistula, which, notwithstanding frequent cleansings, was exceedingly offensive. Dr. Wilbur and Dr. Green concurring, arrangements for an operation were finally made.

Operations for the closure of fæcal fistulæ have not, as a rule, succeeded well. Laying aside the difficulties in working through adhesions, a closure of the gut is seldom effective, while the opening of the tract of the fistula or into the abscess necessarily exposes the abdominal cavity to the dangers of sepsis. I therefore determined not to attempt to find the point of origin of the fistula, but to divide the gut on each side, close the respective ends, and unite the portions of intestine freed from the adherent mass, leaving the latter, together with the tract of the fistula or abscess cavity, undisturbed.

On the 11th of September, five weeks after the abscess was opened, ably assisted by Dr. Wilbur and Dr. Green of Honeoye, Dr. Goodrich of Avon, Dr. Guinan of Lima, and Dr. Starr and Dr. Foster of Rochester, I opened the abdominal cavity at the outer border of the right rectus muscle, being careful not to carry the incision much below a point intersecting a line drawn from the umbilicus to the anterior superior spinous process of the ilium, lest the abscess might be inadvertently opened; but, as no adhesions were found between the colon and the anterior abdominal walls, the opening was extended downward to within an inch and a half of Poupart's ligament, about five inches in extent, in order to allow plenty of room for work. The cæcum and lower end of the ileum were adherent by their inferior and posterior aspect to the iliac fascia, the upper surface being free. A foot or more was thus adherent. The appendix was not found and was presumably the seat of the trouble, having been lost or inclosed within the abscess. The extent of the abscess and exact point of the fistulous opening in the intestine could not be determined by sight or palpation, necessitating the elimination of almost the entire adherent portion—about a foot—including the ileo-cæcal valve. The ends of the divided ascending colon were closed with Lembert's suture of fine silk, the peritoneal surfaces being in apposition, and the ileum, divided

* Read at the meeting of the Ontario County Medical Society, held at Canandaigua, October 14, 1890.

some two or three inches above the valve, was treated in the same way. Flat sponges were placed beneath the gut while it was being operated upon, the contents of the intestine having been previously pressed away and held back by coarse ligatures tied in a single knot for the purpose of being afterward removed. While suturing the ileum it was found that one of the ends of the divided colon leaked, whereupon the end was resutured and the abdominal cavity cleansed. The ileum and colon were then joined by their lateral surfaces by means of Abbe's catgut rings, which I had prepared according to his directions, the suturing being done with fine silk. There was no leakage at any point, and the apposition of the margins of the openings seemed perfect. The parts were cleansed, the abdominal cavity was rinsed, the intestines were replaced (they had been kept warm by means of sponges wet with a warm saline solution), and the walls were closed and dressed in the usual way, the entire operation lasting about an hour and forty-five minutes.

Every antiseptic precaution was observed throughout, yet it seems difficult in such procedures to prevent infection of the peritonæum to some extent, for, in making the openings, the fingers may become contaminated, and the process of suturing endangers the infection of the silk. The fingers may be cleansed, but a thorough sponging of the sutures with an antiseptic solution may fail to neutralize all the germs within or beneath the fibers if they have peradventure penetrated the mucous lining of the intestine. The system undoubtedly, in ordinary circumstances, is capable of resisting a certain degree of virulency, but in certain low states this power is measurably lost, so that death may result from combined shock and septic inflammation, provided there is even slight contamination. Dr. Wilbur informs me that this patient died of peritonitis and shock forty hours after the completion of the operation. There was no autopsy.

The surface temperature never came up to normal. About twenty-four hours after the completion of the operation the rectal temperature had risen to 101°, and twelve hours later to 104°. The pulse, when the patient was put to bed, was 130 a minute, and became somewhat less frequent during the fifteen hours I remained with him. Vomiting was occasional after the operation, and more or less pain was experienced. Tympanites was not marked. Patients frequently recover after as much evidence of local trouble as this patient showed, and there may justly arise a question as to the existence of actual septic peritonitis.

I have been uncertain as to the source of the sepsis, if, indeed, it was an important factor. It was possibly due to insufficient cleansing of the abdominal cavity after the leakage in the colon took place, although at the time it seemed sufficient. The inside of the ends of the cut intestines was sponged out with a 1-to-2,000 bichloride solution, and after the union was completed the stitched parts were well cleansed. There was more exposure of the intestines than was desirable, made unavoidable on account of flatus.

Here let me say, from a considerable experience in abdominal work of one sort and another, that I am convinced that an operation for forming an anastomosis, or in peritonitis, or in appendicitis, is more difficult than an uncomplicated ovariotomy, for the reason that the intestines are always bulging up in the way, and that, with the tense abdominal walls, makes it more difficult to get a nice adaptation of peritoneal edges when the wound is closed. Notwithstanding the instructions to keep the intestines, except the part operated upon, within the abdominal walls, it will be found in most cases impossible to do so, and there is consequently an increased risk from exposure and manipulation.

Pus only came from the fistula after the operation, and at death a rectal discharge of fæces was found to have taken place.

The principle originated by Senn in the lateral anastomosis was followed. Its advantages over end-to-end union are obvious, not only in affording greater security against leakage, but also in being stronger and more rapidly accomplished. Intestinal anastomosis has been successfully performed several times in malignant disease, affording the patient an increased length of rope, and has been successfully performed by Abbe for fæcal fistula; but in no instance, so far as I have seen, has the procedure followed by myself been adopted or suggested. Although this case terminated fatally, owing in great part to the desperate condition of the patient, who was unable to resist the influence of some unknown sepsis, the principle of leaving the fistula itself untouched and uniting the intestine independently seems entirely feasible—indeed, the only course to follow in similar cases.

In cases in which the patient's condition is not too low there is every reason for hope of success; but there is scarcely a procedure which requires greater care and watchfulness on the part of the operator throughout than one for intestinal anastomosis. The surgeon can not always select his cases. He sometimes must take a great risk of failure for the sake of giving his patient the only remaining chance. Moreover, persons will seldom submit to an operation so long as there is any other chance for life.

On account of these things this operation may never present as favorable statistics as some other abdominal operations, but it is none the less legitimate.

(The method of using the rings and plates in forming the intestinal union was then demonstrated.)

A NEW OPERATION FOR DEVIATION OF THE NASAL SEPTUM,

*WITH A REPORT OF CASES.**

By MORRIS J. ASCH, M. D.

The distress occasioned by a permanently occluded nostril in the shape of mouth-breathing and the various complications that accompany this condition is brought so often to the notice of the nasal surgeon that any operation that will easily remedy the difficulty is worthy of notice. The pathology and symptoms of a deviated septum have been so often described that I will not occupy your time with them, but content myself with calling attention to the operative procedure by which I remedy the defect. It is particularly adapted to those cases in which there is a de-

* Read before the American Laryngological Association at its twelfth annual congress.

flection with increased length of the septum, and where there is adhesion to the inferior turbinated body; its great advantage being in its simplicity and in its easy and rapid performance—that it involves no loss of substance and entails but little annoyance to the patient after the operation. I have found the operation to be perfectly satisfactory, permanently relieving the obstruction in all cases; only those in which there existed deflection of the bony septum discovered after the correction of the cartilaginous deformity required any further treatment. In one case only was there any hæmorrhage of a severe character, which was easily checked; and in one case—not among those here reported—there remained for two or three years a small perforation which has since healed.

In all of these cases the deviation of the septum was toward the left, a fact in accord with the observation of most writers.

The instruments I employ in this operation are—

1. A pair of strong cartilage scissors, one blade thick and blunt for introduction into the obstructed nostril; the other, the cutting blade, of a curved wedge-shape, the shanks curved outward so as to admit of closing without interfering with the columna. The handles are of steel and curved, like those of a dental forceps (Fig. 1).

2. A curved gouge for breaking up any adhesions that may exist between the septum and turbinated body (Fig. 2).

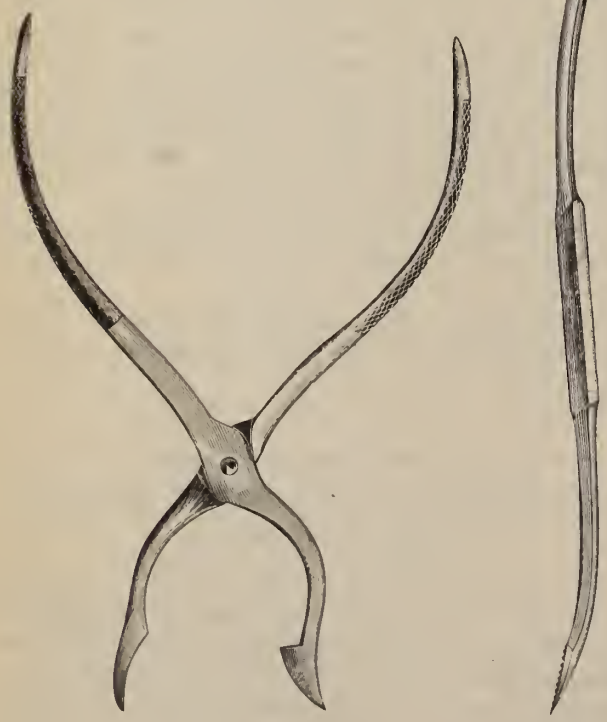


Fig. 1.

Fig. 2.

3. An Adams forceps, or one with stout parallel blades.

4. A triangular splint of tin, cut to adapt itself to the cartilage of the section. Formerly I used a splint of a more elaborate character, such as I show you here (Fig. 3); but it had the objection of being always in sight and I gave up its use, although in other respects it proved perfectly satisfactory. If the patient has a good deal of nerve, the operation may be performed with the aid of cocaine; but, as a rule, it is best to use ether. Before the operation the nostrils are to be well washed out with a disinfecting solution, such as listerine or, what I have been accustomed to use, Dobell's solution with the addition of thymol and eucalyptol. The patient then having been etherized, the adhesions between the septum and turbinated body, when such exist, are broken up by the use of the curved gouge. The blunt blade of the scissors is inserted into the obstructed nostril, and the cutting blade into the other; a crucial incision is then made as near as possible at right angles at the point of greatest convexity. The forefinger is then inserted into the obstructed nostril; the segments made by the incision are pushed into the opposite one, and the pressure continued until they are broken at their base and the resiliency of the septum destroyed. On this point depends the success of the operation, for, unless the fracture of these segments is assured, the resiliency of the cartilage will not be overcome and the operation will fail. The septum is then to be straightened with the Adams or other strong forceps, and the hæmorrhage checked before proceeding further, which is usually accomplished by a spray of ice-water, though sometimes tamponing may be required. The nostril having been cleaned, the straightened septum is then held in position by the tin splint previously wrapped with absorbent cotton moistened in a solution of bichloride of mercury of 1 to 5,000, and the nostril packed with gauze or absorbent cotton moistened with the same. The tamponing must be thoroughly done or hæmorrhage will certainly recur. I usually introduce a pledget of gauze or cotton, to which a ligature is attached, as far into the nostril as is possible, leaving the string hanging out, and pack the moistened pledgets firmly upon this. The splint and tampon is allowed to remain undisturbed for four days, when they are removed and the parts cleansed with a disinfecting solution; the splint and tampon are then reapplied, the parts being straightened, if necessary, with the forceps. This is repeated two or three times a week for three weeks, by which time the parts have become permanently fixed in their improved position; but it may require at least two weeks more before the parts are healed and the patient breathes through an unobstructed nostril. It sometimes happens that posteriorly to the cartilaginous deviation a bony one exists. This can then be easily remedied by the electro-trephine or saw. The cases which I report here were all, with one exception, operated on at the New York Eye and Ear Infirmary, and the after-treatment was carried out by Assistant Surgeon Dr. Emil Mayer, to whom I am indebted for their report. I have delayed presenting the report of this operation to you until I had assured myself that its results would prove satisfactory and permanent; but now that the operation has stood the test of time, I feel that I am justified in doing so. The operation is simple and easy, requires but a few minutes for its performance,

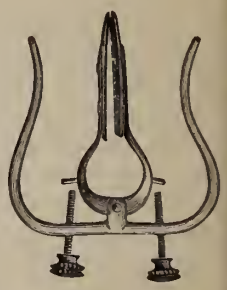

Fig. 3.

involves no loss of substance, and the operator is not embarrassed in his work by the bleeding—a practical point which I am sure all who are familiar with nasal surgery will appreciate. Of the cases reported, the incisions in the first two were made by the bistoury instead of the cartilage scissors, but the principle of the crucial incisions with fracture and tampon was the same.

Case I.—A. W., female, aged eleven, patient of Dr. Mayer's, was brought to New York for treatment for nasal stenosis, said to be due to a fall in infancy. The cartilaginous septum is deviated to the left near the orifice of the nostril, which is completely obstructed, no air passing. She is a mouth-breather, and the voice has a nasal twang. Operation performed under ether on September 19, 1883. The crucial incisions were made with a knife through the cartilage, the fragments fractured, and the nostrils plugged with antiseptic cotton, which was removed on the third day. There had been no bleeding and no rise of temperature. After washing out the nostril, the left side was repacked, the parts being kept straight with the Adams forceps. On September 30th plugs removed: patient breathes freely through both nostrils. The straightening forceps are introduced tri-weekly, and on October 24th patient is discharged cured.

Case II.—Louise H., aged seventeen. Patient of Throat Clinic, New York Eye and Ear Infirmary. The left nostril is completely obstructed by a deviated cartilaginous septum, which is firmly adherent to the inferior turbinated body of the same side. Operation performed at infirmary, September 28, 1884, under ether. The adhesions were broken up, and the crucial incisions and fracture accomplished. The septum straightened, and held in position by a specially devised splint (Fig. 3). This consisted of an external, lyre-shaped frame, to the center of which, on a hinged joint, two plaques of hard rubber, of a shape similar to the triangular cartilage, were attached. The plaques, being adjusted to their place in either nostril, were fastened in their position by the screw passing through the outer frame, and the nostrils afterward tamponed. There was no constitutional disturbance. In three weeks after tri-weekly applications of the straightening forceps the patient was discharged cured.

Case III.—Philip L., aged thirteen, came to the clinic of the New York Eye and Ear Infirmary with nasal obstruction; is a mouth-breather. Hearing defective in left ear; is dull and apathetic; the cartilaginous septum is deviated to the left and is firmly adherent to the inferior turbinated body, the greatest convexity being an inch and a quarter from the nasal orifice.

The operation was performed under ether at the infirmary, December 1, 1888. The adhesions having been broken up by the gouge, the cartilage was incised with the cartilage scissors, the segments fractured, and splint and tampon applied. After the cartilage was straightened, a long, bony obstruction was found to exist behind it, which was afterward removed by means of the electro-trephine. This was finally accomplished in six weeks, and on February 15th the patient was discharged cured, breathing freely with closed mouth, and hearing greatly improved. A recent report from this case shows the improvement to be permanent.

Case IV.—Fannie M., aged sixteen, came to the clinic of the New York Eye and Ear Infirmary complaining of nasal obstruction and deformity, the result of violence when three years old. Examination shows the left nostril to be entirely occluded by a deviated septum, the tip of the nose being bent to the right. She is more anxious to be relieved of the deformity than of the obstruction. The operation was undertaken with the view of curing both. Operation at infirmary, December 22, 1888, under ether. Crucial incisions, fracture, splint, and tampons. After straightening the septum, a strip of rubber plaster was applied to the tip of the nose, and traction made by fastening the end to the left cheek. The traction was faithfully kept up for some weeks after the patency of the nostril was re-established, and when seen on May 4, 1890, by Dr. Mayer, the deformity had entirely disappeared.

Case V.—Julius R., aged sixteen; clinic of the Manhattan Eye and Ear Infirmary. Operation, under ether, May 22, 1889. Operation and after-treatment as in the other cases. Discharged cured on June 15, 1889.

Case VI.—B. R., male, aged seventeen, referred to Throat Clinic of New York Eye and Ear Infirmary by Dr. Rupp, surgeon in the Ear Department. The patient is entirely deaf in left ear. Left nostril completely occluded. Operation, under ether, February 8, 1890. Same procedure as in previous cases, the resulting hæmorrhage, however, being more than ordinary. During the night succeeding the operation his breathing was alarmingly interfered with during sleep. On being awakened by the nurse, he was found to be bleeding from the mouth, and large coagula were expelled from the pharynx. The tampons were removed, the nose cleansed, and the bleeding checked by ice, after which the splint and tampon were replaced. On the 7th hæmorrhage recurred during the night, but was checked by ice. On the 15th he went to his home, when bleeding again occurred, which was controlled by my assistant, who was sent for. After this there was no further trouble, and the regular after-treatment was carried out. On March 20, 1890, Dr. Rupp reports marked improvement in the hearing, and on April 30th the patient reports that he breathes freely through the formerly obstructed nostril.

A NEW LOCAL THERAPY OF TUBERCULOSIS PULMONALIS.

By HUGO J. LOEBINGER, M. D.

Never before has the question concerning the curability of consumption possessed more intense interest than at the present time, when scientists of all nations are striving to solve the problem of the cure of not simply pulmonary tuberculosis, but tuberculosis generally; and it almost seems as if its realization were at hand.

The reason for this general emulation lies in the fact that since Koch's discovery of the *Bacillus tuberculosis* our knowledge of the cause of the disease has become more comprehensive; and that, in particular, the study of the life-giving properties necessary to the existence of the bacillus, through the cultivation of pure specimens and after experiments upon animals, warrants the hope that its growth in the organism may be cut off—which the above-named scientist, Koch, is alleged to have already in a measure accomplished. At all events, we have learned, particularly since the latest investigation by Cornet, and others before him, to protect ourselves against them.

Another reason is the fact that Nature often effects a spontaneous cure of pulmonary consumption, if only in its first stages.

Attention is here called to the interesting records of post-mortem examinations at the Paris Morgue, published by Vibert, which treat of the sudden or violent death of

numerous apparently healthy persons whose lungs, however, simply showed evidences of healed tuberculosis. Clinical experience has confirmed the partial curability of tuberculosis of the lungs and unconditionally recognizes this. Only with regard to the therapy is there a division of opinion, which runs in two channels. One theory is that of general therapeutics, which consists in the belief that it is better not to attack the *locus affectus* directly, but rather, by means of general regulations—such as good, even excessive, food, pure air, permanent sojourn in the open air, etc.—to effect, as it is asserted can be done, the patient's restoration. As an extreme measure, internal aid is given to act on the disease through the circulation of the blood, as, for instance, by the use of creasote, guaiacol, etc. Interpreted into the language of modern bacteriology, this means to rob the *Bacillus tuberculosis* of the soil which promotes its growth. These views are strengthened by the happy results attained in those institutions and establishments where such principles are strictly maintained. In Europe the most renowned of these are those of Dr. Driver, in Rippoldsgrün; of Dettweiler, in Frankenstein, Taunus; the Bremer's institute in Görbersdorf, etc. Of those institutions in the United States enjoying transatlantic reputation, Dr. Trudeau's Adirondack Cottage Sanitarium is the leading one.

Opposed to this theory are the more or less negative results of that therapy which has for its first principle the attack of the *locus affectus* directly—the local therapy. It is true that, since the failure of hot-air inhalation, etc., there exists among our physicians, as well as in the public mind, a certain amount of distrust of all so-called local cures for pulmonary consumption. Nevertheless, it must be conceded *a priori* that that point of view will be an ideal one with respect to lung therapeutics (including, also, general therapeutic regulations) which does not prohibit the local treatment of the diseased lung. This is therefore a surgical view of the question; precisely as a surgeon would not content himself with undertaking the treatment of a fungous inflammation of the knee joint simply with fresh air and nourishing food, nor even with a general contratuberculous cure, by means of inoculation, etc.

At the last International Medical Congress one of the greatest throat specialists of Europe, Professor Heryng, of Warsaw, most emphatically declared that no general contratuberculous cure should ever deter him, in cases where local therapeutics was available, from energetically employing the same; as in the larynx, for instance.

Overlooking the somewhat venturesome attempts to inject medicinal liquids through the thoracic wall into the lung (which practice has led to unfavorable results, with hæmoptysis, pleuritis, etc.), local therapy should be employed only by means of the natural channels of respiration. It has consisted, heretofore, merely in some form of inhalation. Effective inhalation has only been undertaken with real gases when it could be foreseen that the same would really reach the lung tissues through respiration.

The choice is, unfortunately, very limited, as the majority of gases are partly irrespirable—*i. e.*, they cause spasm of the glottis—partly irritating and toxic; wherefore the selection has been confined to the most natural and accessible of gases—viz., the atmosphere and its single constituents. Heated air has been resorted to, as the bacilli can not live in a certain degree of high temperature—as if it were possible for the lungs, a by no means unimportant part of the entire body, to, even for a moment, maintain a higher level of temperature than that of the body! The results, therefore, remained not only entirely negative, but it was also demonstrated experimentally by Mosso, of Turin, that even with inhalation at 320° F. the temperature in the trachea of a dog, with a body temperature of about 102° F. in the rectum, showed 100° F.; so rapid is the process of cooling in the air channels.

The several component parts of the air, oxygen and its modification ozone, and nitrogen and its modification azote, have been applied as inhalations in the treatment of pulmonary consumption. The former, it is well known, influences the blood-corpuscles, and thereon depends the entire change of matter. The inhalation of oxygen results in a more rapid diminution of oxidation stages. Whether this has a desirable influence on pulmonary consumption, in that an accelerated change with negative balance leads to a rapid end, is a question that can readily be answered. Ozone has undoubtedly (Liebreich) an eminently antizymic virtue; still it operates more intensely than oxygenium upon the blood globules, being at the same time very irritating. Besides, through the operation of vegetable germs existing in the superior air-passages, it is restored to its original molecular composition. Rarefied oxygen, so-called nitrogen (or azote), though hindering the decay of the diseased organism (like a sojourn in a high climate where the air is thin and rarefied), yet, as regards its influence upon the process of the disease itself, seems to be without any direct effect in its cure.

Concerning the so-called vapor inhalations, medicaments dissolved in water—for example, creasote, carbol, etc.—it appears highly problematical whether the matter inhaled really reaches the lung tissues. Even should we not rest satisfied with inhalations of dispersed liquids, but resort to medicinal liquids really heated up to the boiling point, so that the matter would be transformed into vapor in the same proportion as when dissolved, the intended result seems questionable. The same applies to the spray inhalation lately recommended by Jahr, wherein heated air is intimately mingled with the dispersed atmosphere, so as to allow the atmospheric fluids to evaporate, a process not far different from the actual vapor inhalation. The latter, if applied rationally and for the purpose of respiration, commingled with cold air, is primarily exposed to becoming cool, which coolness in the trachea, as above shown, becomes excessive. And as, in consequence of the breathing process, there is continually present in the air-passages a large quantity of liquid, the point of satiety is more speedily reached. The vapor is rapidly condensed and falls again in drops.

Other mediums of solution—like alcohol, ether, chloroform, etc., the boiling point of which is much lower than that of water, and of which we may infer, therefore, that, as soon as they are transformed into gases, the same will be saved until reaching respiration in the lung tissues—are, be-

cause of their relative appearances, useless. At the same time, up to the present, creasote, for instance, has been the most desirable contratuberculous remedy, being easily soluble in alcohol or in ether, but soluble, however, only in 110 parts of hot water.

From the foregoing it is deduced that vapor inhalations do not penetrate into the lungs; thus they are advisable only in the treatment of diseased larynx, trachea, and bronchi. Indeed, in these cases there is no method or treatment that can displace this. But even with pure gas inhalation it is questionable whether the gases reach the *locus affectus*. Aside from the difference in the gases, the propelling motor of the inhalation is, practically, the respiratory movement; we know that not simply the diseased spot of the lungs remains in a state of inactivity, but also the neighboring organs, in consequence of relaxed tension, being extremely sore and painful, and therefore aiding but little in the respiratory movement, the result being that the healthy portions of the lungs are obliged to suck up more strongly the inhaled gases, and these, not being intended for them, cause irritation and often pernicious results. This physical fact is not changed by the use of compressed air or gases for inhalation.

How, then, is it possible to act with purely local effect upon the actual seat of disease in the lungs?

The primary requirement is the acknowledged one of first locating the seat of disease, then to circumvent the same after a thorough physical examination, not resting content, in consequence of the discovery of the bacilli found in the sputum, with the general diagnosis—tuberculosis pulmonalis. Proceed then to ascertain the form in which medicinal substances may be conducted direct to the diseased portion of the lung tissue and there remain, in order to discriminate between the inhaled gases (whose contact with the seat of disease must of necessity be transient) deposited for a certain length of time, so that not merely a transitory effect will have been attained. And this is in the form of powder! Can powder (or dust) be conveyed into the lungs?

Since Cornet's investigation, we know that the germ of the disease—the *Bacillus tuberculosis*—is conveyed into the lungs in the form of dust; therefore the remedy, in order to reach the seat of disease in the lung, must exist in this form. The dust of rooms and streets, daily inhaled, only in part remains in the superior air-passages, from there to be again expectorated; a portion penetrates into the lung-parenchyma, where, at autopsies, it is often met with, representing a portion of the pigment of the lung.

Who has not heard of the so-called anthracosis (coal lung), or pneumonokoniosis, and siderosis of persons following certain vocations? It is remarkable that here the inhaled dust—provided, of course, that the same is free from all infectious admixture—following a purely mechanical path, will cause, first slight, then more aggravated, lesions in the tissue, frequently resulting in chronic absorption of the lungs, and, being in the form of so-called fibrous induration, occasion cicatricial formations in the interstices of the tissue (viz., interalveolar, interbronchial, and subpleural), with consequent shrinkage.

That which is here characterized as a pathological phenomenon is that art of natural cure which seeks to eliminate and make innoxious the destructive micro-organisms by means of reconstruction of the connective tissue of the lungs, producing an actual cicatricial formation, taking the place of the decayed lung parenchyma, which often occurs spontaneously in pulmonary phthisis. Wherefore it is well to work upon this plan, indicated, as it were, by nature.

In insufflation of the lungs we make use of a compound powder whose basis for the purpose of mechanical action in the diseased tissue is calcium phosphide, which becomes an amorphous powder, insoluble in water, that, when deposited in the lung tissue, is also imbibed by the lymph cells, which, in turn, become migratory amœboid cells, carrying the powder through the interstitial tissue, and finally gaining a foothold in the filter apparatus of the large bronchial lymphatic glands.

It naturally follows that a portion of the calcium phosphate, mingling with the albumin of the necrosed tissue, which possesses everywhere in the body a well-known chemical affinity for calcium, becomes chemically united with it, representing calcined lime in the cheesy portions. Upon this premise it has often been given internally for scrofula and tuberculosis, and also frequently applied externally in cases of tuberculous ulcerations, strewn thereon in the form of powder.

I beg here to call attention to the observations made by Halter, the originator of hot-air inhalation, that, in districts where phthisis abounded, those employed in lime-kilns remained, during a period of fifteen years, exempt therefrom. Halter attributes this fact to the influence of the hot air present. How can we explain, then, the fact that persons working in a much higher temperature—as, for instance, in furnace-rooms—do not have equal immunity?

Excluding all specific effect, it must be conceded that from these particles of calcium phosphide proceeds that mechanical irritation which gives to the diseased lung renewed vigor, favoring the reconstruction of the connective tissue of the lungs. That the effect may be a purely local one—that is, that the sound lung tissue may be spared—will be hereafter touched upon.

To satisfy the demands of antisepsis, which, without first seeking a specific against the *Bacillus tuberculosis*, promises success in view of the fact that phthisis of the lungs, being a mixed process, where other pathogenic bacilli also come into play, such as, for instance, varieties of streptococcus, sodium benzoate may be mentioned as a second constituent for the powder mixture. As the latter is soluble in water, the effect is not a mechanical but a chemical one. Without expecting, as P. von Rokitansky erroneously assumed, a specific contratuberculous effect, it nevertheless possesses great antizymic strength, acting in a stronger degree than the pure acid.

According to Buchholz, 0·05 to 0·06 per cent. of this salt, in the nutritive liquid used by him, proved sufficient to prevent the growth of bacteria. But subsequently Schreiber, after giving internally fifteen grammes, observed only insignificant results, such as dizziness of the head and

a heightened pulsation of the heart. Sodium benzoate is soon eliminated from the body, partly in its original form, partly in the form of hippuric acid.

Our third and most significant constituent is either one of the ethereal oils, in the shape of an elæosaccharum, so that the whole may form a fine, amorphous powder; for the powder consistence is lost if the oleaginous constituents rise above ten per cent. Formerly they were used simply as an addition, essence, or perfume, except by the old Egyptians, who used the same for embalming their dead; with the exception, perhaps, of the heavier metallic compounds—such as those of mercury, silver, and gold—they now stand pre-eminently at the head of all antiseptic and specific contratuberculosis substances, according to Koch and others. For example, Koch found that oil of peppermint, in a solution of 1 to 33,000, was sufficient to kill anthrax bacilli, while Chamberland, Meunier, and others observed that oil of cinnamon, in its action upon typhoid bacilli, was equal to a mercurial sublimate solution of 1 to 200. This is not surprising when we consider that the ethereal oils are formed from terpenes, which, while causing some reduction, produce hydrogen dioxide, which possesses antiseptic powers; and from camphors, the contratuberculous effect of which has recently been demonstrated by Marpmann experimentally. After having administered several chemical camphor preparations to rabbits, Marpmann succeeded in making them proof even against inoculation of the *Bacillus tuberculosis.*

As soon as the powdered mixture is deposited the intermixed ethereal oils pass away, in the form of vapor, from the particles to which they clung, and enter the neighboring diseased tissue.

This is an important fact, for, if cavities do not exist which communicate with the bronchi, then, in the most favorable case, the powder will reach only to the vicinity of the *locus affectus*, which generally lies apart or excluded, and not directly accessible by way of the respiratory passages. The transpiration of the internal evaporation of oils, for which the less important powder admixtures represent the vehicle only, is termed by me "secondary internal inhalation."

The average proportion of the individual constituents is variable. For example, where the treatment of cavities is concerned, or an aggravated irritation in the trachea, the quantity of calcium may be rated proportionately low; it is proportionately high, however, in cases of chronic, cheesy pneumonia, where there is already a proneness to cicatricial formation with shrinkage.

Although insufflation is generally relegated to the simplest medicinal province, the following difficulties are enumerated herein, which, however, can be very readily overcome by any practical and skillful physician:

The first step is to pass through the narrow passage of the larynx, whose *glottis respiratoria*, in regular breathing, forms a fairly triangular opening; the same becomes extended, however, in forcible inhalation to a square, which, by means of the insertion of a laryngeal mirror, permits a deeper view into the trachea, as far as its bifurcation.

Instruct the patient, therefore, to take a deep breath at a given signal while stretching forth the tongue so as to raise the epiglottis, which covers the *aditus laryngis.* Into the mouth thus open a very thin tube is inserted, the end of which is bent at about a right angle, with the opening perpendicularly over the *aditus laryngis.* Naturally, the tube must lie exactly in the median plane and in the axis of the trachea. The propelling force must be sufficiently strong, so that, notwithstanding any resistance, the powder may really be thrown into the depths of the lung tissue, and with such rapidity that not the slightest evidence of suffocation will appear. This procedure may be simplified by having the tube of the smallest possible caliber, so that the powder reaches the superior air-passages in the form of no more than a thin ray—a circumstance which avoids, at the same time, any irritation. It is well to mention here that the ordinary powder insufflator, with hand-bellows attachment, had better be avoided, as the compression necessitates a waste of time, and use made instead of the one customarily employed for that purpose—viz., Livingstone's pneumatic spray producer,* with the assistance of which a power of from fifty to sixty pounds to the cubic inch is developed.

As the propelled powder pursues a straight line—like shot—it must pass through the *aditus laryngis* directly to the seat of disease beyond; for without particular caution it would not pass beyond the bifurcation. This difficulty can be obviated by the position of the patient himself, which may be so arranged that the powder will reach the seat of the disease directly. If the latter is located on the left (back) side, the patient assumes a position as follows: Body bent forward to the right with head thrown back, which last position is commended, in order to mitigate as far as possible the force of the propelled powder against the walls of the pharynx. In this position the patient must practice respiration. While, therefore, the healthy or less affected side is compressed by the simultaneous closing of the bronchial opening by this position, as well as by the synchronism with the respiration resultant from the elevation of the arm on the same side, besides extending the bronchial tree, the latter can in this manner regain its excursional functions, and will also, as a matter of fact, increase the lung capacity.

It is remarkable that the (among males) typical abdominal respiration may in this position be excluded, and the superior segment of the thorax, in the ulterior lung portions of which is usually located the seat of the disease, is especially benefited by this lung gymnastics. These experiments must, of course, be practiced with great caution, particularly in the beginning, to prevent hæmoptysis.

Naturally, the greatest care is necessary on the part of the physician, so that the powder to be applied may be applied not a moment too soon or too late, for in either case the glottis, closing prematurely, will cause the powder to become fixed in the larynx. Further consequences would be apparent irritability in the superior air-passages, etc. On the other hand, there is the assurance and satisfaction of knowing that the powder, owing to the peculiar position

* Made for my purpose by E. Ackermann, of No. 153 West Twenty-ninth Street.

of the patient, arrives only in that particular part and neighborhood of the lung which is diseased. In fact, patients themselves designate the exact spot where they feel the air entering, they having long felt a burning sensation within the thorax, caused by the admixture of the ethereal oils, thus excluding any error in indicating the spot.

Also, by means of physical examination, co-operation may be obtained. For example, in the case of a patient, above a circumscribed spot of the left upper lung I observed a peculiar respiratory whistling, which disappeared after every application, giving place to a rattling sound.

Are these observations worthy of therapeutic experiments? What have been the practical results obtained during the past year and a half in those cases undertaken by the writer, with a view to curing pulmonary consumption?

I will refrain from here going more specifically into the history of all the cases; they will be treated of in detail shortly; besides, minute explanation of the method of the cure will be given. But I affirm that, of the numerous cases of pronounced pulmonary phthisis which have been subjected to this treatment, there have been but few negative cases to record, and these but apparently negative, as the treatment was not continued long enough.

One of these cases, for example, was that of a young girl who was so nervous that the vocal cords under the laryngeal mirror were in a continual state of vibration; here, of course, the powder could not reach beyond the larynx. Where, however, treatment was possible (and it is never required for a longer period than three or four months), improvement was observable until the disappearance of the bacilli, except in one case; and gradually the cough and expectoration ceased and an increase of flesh was apparent. After that it was possible to undertake the physical treatment or cure of the diseased portions within which the desired cicatricial formation had taken place.

Lack of space permits the particular citation of but two cases, taken from the records of the histories to be published. Among the numerous cases they are represented as Case I and Case VIII.

Case I.—Mr. P., engineer, Scotch, forty-five years of age, for twelve years suffering with pectoral complaint. For a period of three years there has been increased suffering, with a rapid decrease of bodily strength. The most eminent medical authorities consulted; diagnosis, phthisis pulmonalis. Several months' sojourn in the South without beneficial results. Afterward several months' sojourn in a private hospital for consumptives, from which he was discharged as incurable.

Status præsens, December 5, 1889.—Patient is tall and narrow-chested; in a very wretched condition. Worn almost to a skeleton and so weak that he can not walk without assistance. So short of breath that speech is extremely difficult. Complains of a continual cough. Expectoration and severe stomach pains; frequent night sweats. Left half of thorax crippled, in consequence of the uneven healing of a rib fracture. Scarcely exercises the respiratory organs. Extreme dullness of the front half of the thorax. In the back, on the same side, a tympanitic sound. In the anterior and ulterior parts, continuous rattling sounds. Profuse expectoration; numerous elastic fibers; individual bacilli. Treatment began December 7, 1889. Respiration, 40; weight, 115 pounds.

Though the patient is quite exhausted and respiration extremely weak, he nevertheless seems fit for the treatment about to be practiced, and undergoes, several times a day, the above-described gymnastics for the lungs. First insufflation, December 14th; repeated on the 17th and 18th. Each time this powder is applied three times in succession; patient feels the strong current of air in his breast. Cough and expectoration rapidly improve; particularly, the patient declares that expectoration no longer causes any effort, as formerly. On the 20th, appetite good and a gain in bodily strength. Respiration, 32. After practicing this lung gymnastics two weeks a decided increase is shown in that half of the thorax which was almost in a state of cessation as regards its respiratory excursional functions. After an attack of influenza, exacerbation follows as regards all the symptoms, consequently causing a relapse. Patient was bedridden for a time. After resuming the lung treatment of the now thoroughly exhausted patient, on the 5th of January, 1890, cough and expectoration appeared to return almost in their original form. But few bacilli found; distinct movements of the diseased side of the thorax. From this time forth, all through January, daily applications. The powder was found to have reached the inferior lobe of the lung, latterly to the superior, and finally to the apex.

After a time the bodily strength increased; slowly cough and expectoration passed away, and finally the bacilli, never profusely present, disappeared altogether.

The following is cited as an illustration: The inmates of adjoining rooms, having become accustomed to the continual cough of this patient (most severe at night), after the same ceased, often inquired whether death had already relieved him of sufferings.

Status præsens, February 2, 1890.—The patient, whose face formerly showed sunken eyes and prominent cheek bones, presenting a frightful appearance, has, through the accelerated and violent respiration, found adequate relief, and now seems livelier and happier, being scarcely recognizable as the same man. Respiration, 24 a minute; coughs only early in the morning; is more active. Expectoration almost gone. During the day and night no coughing. Increase in weight, six pounds. Patient walks without assistance. Can converse also for some length of time without fatigue.

Results, as above stated, after examination. On measuring by means of the calipers, decided change of the sterno-vertebral diameter (about one centimetre) in the second intercostal space. The acquired lung capacity measured with spirometer. Left side, tympanitic echoes, slight sounds of rattling.

A continuation of the treatment until the middle of March, with slight interruptions, kept the lung symptoms unchanged; the general condition somewhat wavering, in consequence of periodical stomach trouble and loss of appetite. Formerly the gastric troubles often reached a high degree of intensity. Dismissed and treatment discontinued. The patient accepts a position in the South, whence he returns after three months. Since discharge has become stronger; insignificant stomach trouble; steady increase in weight. Patient coughs now and then in the morning, with slight discharge of phlegm. Mr. P. is able to follow his vocation without exertion. His only complaint now is of frequent palpitation of the heart; also, objectively, there is observable an increase of cardiac dullness.

Résumé.—It is remarkable that the improvement of all symptoms is so rapid in the first week, while after that the progress is, comparatively, much slower. Nevertheless, the recovery of a man so completely in a decline and so full of suffering is assuredly remarkable. Perhaps this might be

explained by stating that this case, because of the scarcity of the presence of bacilli and the extreme shrinkage of the left lung, was peculiarly adapted to such therapeutics, which becomes still more strengthened during the treatment by elimination of the *causa efficiens;* withal, the increase of the hypertrophy of the heart is in unison with the foregoing.

Case VIII.—Miss P. J., thirty-three years of age, ailing for many years. At first simply chlorosis and stomach weakness; later, catarrh of nose and throat. Finally, for the past seven years, pulmonary symptoms, such as cough, expectoration, chest depression, etc. At first only in a limited degree, but during the past three years continually increasing, accompanied by rapid decline of bodily strength, gradual lessening of appetite, etc., with frequent fever and night-sweats. The patient was formerly forewoman in a large mercantile house, but for some time past incapacitated for work, often being obliged to keep to her bed.

Status præsens, February 17, 1890.—The patient is a small, slight person, with a pale, thin face, causing her to appear much older. The left half of the thorax remains remarkably impassive while breathing; the second and third intercostal space seems to be particularly sunken; over the same, moderate dullness with weakened respiration and dry rattling sounds; bronchial respiration over the apex of the lung. The right lung is apparently unaffected; patient complains of frequent coughing, especially at night, yet expectoration is insignificant. Microscopic examination, repeatedly undertaken, discloses few scattered bacilli. Patient complains of severe indigestion, weakness in the feet, etc. In the exercising process the patient proves very clever. As there are no cavernous symptoms, but rather chronic, running, cheesy pneumonia in the left upper lobe, accompanied by shrinkage, a larger admixture of calcium phosphide is resorted to.

It is interesting to note that the patient after every insufflation, indicating accurately the spot in the thorax where she feels the inhaled air passing, becomes exhilarated, and immediately after prompted to repeated, energetic respiration, without causing cough or irritation. The application is made daily for a period of four weeks. Within this time a very great improvement is evidenced in the cough. Expectoration becomes proportionately small; disappears entirely after a short time. Within a fortnight after, the cough wholly disappears; but, notwithstanding, the treatment is continued. Presently, too, the general health improves. Fever and night-sweats cease, appetite returns, and proper nourishment results in satisfactory progress. Patient feels very much strengthened, and an increase of four pounds has taken place. Her face has grown plump, shows color, altogether causing her to appear much improved. A deficiency of breath after active exercise is now her only complaint. Worthy of note is the fact that the difference in the sagittal diameter of both sides of the thorax, measured with calipers in the mamillary line, is now equalized. The respiratory sounds in the parts which were affected still somewhat weakened. As an after-cure, the patient will sojourn for a few weeks in a mountainous district. Her condition was still more improved on her return. In the morning only there is slight expectoration, but no cough, and that the patient rightly attributes to throat and nose catarrh, which has not yet disappeared. The latter will, however, now be successfully treated. At present (November, 1890) the patient is entirely restored to health.*

* Several other cases, with more or less extensive cavities, also show healing within a period not much longer.

In conclusion, it is desirable to emphasize that this issue is based upon a practical experience in local therapy of pulmonary disorders, which, it is admitted, excludes from consideration any complications caused by the presence of the *Bacillus tuberculosis* in other organs.

On the other hand, this local treatment of the lungs in the form of insufflation, which, so far as is known, has only been used by Martel in the form of calomel insufflation, may likewise be considered with regard to other pulmonary disorders—for instance, gangrene of the lung, etc.

1055 Lexington Avenue.

THE MIMICRY OF ANIMAL TUBERCULOSIS IN VEGETABLE FORMS.*

By E. F. BRUSH, M. D.,
MOUNT VERNON, N. Y.

At one time I became deeply interested in reading the travels of Livingstone and other brave and noted explorers of Africa, and, while my mind was full of the wonders and mysteries of the Dark Continent, I met a gentleman who informed me that he had resided many years in Africa. I tried to obtain from him some information which I had been in search of. I spoke of the geographical problems to be solved and the difficulties to be surmounted in civilizing that enormous continent, and the whole burden of his comments was that Africa was a great country and would be easily civilized and all obstacles overcome if it was only properly drained. Now, this man's residence in Africa had been confined to the west coast, where the notorious swampy and malarious districts lie, and, because he had not traveled farther or interested himself in the travels of others, he imagined that all Africa was like that portion of the country which he did know would be the better for draining.

We should all naturally be surprised at the narrowness of this man's views, who imagined that an immense continent with snow-capped mountains and rainless deserts of vast extent could be judged from the narrow limits of a malarious swamp, where he had resided for a few years; but, on reflection, the idea could not but occur to me that we medical men, in our studies of the Dark Continent of disease, were often as narrow in our views as this man was in his views of Africa. For instance, a very few years ago Koch discovered in a tubercle numerous bacilli, and straightway we fancy that the tubercle would be harmless if it were only drained of its bacillus, and we put ourselves to work with hot air, rectal injections, medicated inhalations, etc., imagining all the time that we could subdue this terrible and mysterious disease and settle all the difficult questions of pathology connected therewith by simply eliminating from the economy the bacillus of Koch. The bacterial region is emphatically now our place of residence; we wade through swamps of pus, blood, and morbid tissues, pushing aside all other forms and vital processes, after the beckoning specter of a bacillus, and, when we find it, flatter our-

* Read before the New York State Medical Association at its seventh annual meeting.

selves that we have reached the goal and discovered all that is necessary to conquer a disease associated with this small organism. We hardly inquire how it gained its position, what its functions are other than what we imagine as being concerned in the causation of disease, but accept it as the spirit and soul and prime factor in the cause of pulmonary tuberculosis. Happily, the tendency now is to break beyond the bounds of this narrow bigotry; hence I think that a study of some of the vegetable forms that closely mimic animal tuberculosis will help us in our march beyond the narrow swamp through which we are still struggling.

One of the vegetable diseases which mimic very closely tuberculous animal processes is seen in the nut-gall. The nut-galls are truly tubercular processes affecting the breathing apparatus (leaves) and the nutritive channels (roots) of plants. These galls are among the most puzzling of natural phenomena. It is actually known that the *Cynips*, or gall-fly, a small insect of the hymenopterous order, punctures the leaf of a plant or tree, and there deposits an egg, injecting at the same time a very minute drop—the animal itself is only one tenth of an inch in length—of what is described by entomologists as a poison, but which is, beyond doubt, a digestive ferment. This fluid, injected by the insect into the cavity that holds the egg, affects the nutritive process of the plant in such a preponderating manner that it allows the egg to rest in the cavity without the irritating results of the intrusion of a foreign body, and the extraordinary nutrition caused by the ferment goes on to form the tubercular mass known as a gall.

Far more interesting and more closely analogous to animal tuberculosis is the disease attacking the grape-vine caused by the insect called *Phylloxera*.* Can anything in plant-life more closely resemble a human tubercular lung than a leaf of a grape-vine with the galls of *Phylloxera*? "In August, 1885, Luiz de Andrade Corvo presented a paper to the Academy of Sciences in which he asserted that the vine disease ascribed to *Phylloxera vastatrix* was really due to a bacillus, or rather, according to his description, to a bacterium, which is always found in the tubercles of the radicles and in the tissues of the vine which are affected by this disease, termed by him *tuberculosis*. They are also found in the body of the insect, which thus becomes simply the agent of contagion."†

Now, has not this author narrowed his views down to the bigotry of bacilli-worship? The presence of a bacterium in this disease of plant-life is only one of many phases of a morbid process. The bacillus he discovers here is merely the nutritive ferment deposited by all gall insects, and often, as we have already said, called a poison. The *Phylloxera vastatrix*, like the *Cynips quercus*, wounds the leaf, deposits its egg in the wound, and, besides, injects the bacterium which is the nutritive ferment that produces the gall which characterizes the disease. The following sketch of the natural history of the *Phylloxera* is taken from John Henry Comstock's *Introduction to Entomology*: "The grape *Phylloxera* hibernates in the roots of the grape mostly as a young larva of the first or sedentary, agamic, wingless form. With the renewal of vine growth in the spring this larva moults rapidly, increases in size, and soon commences laying eggs. These in due time give birth to young, which soon become agamic, egg-laying mothers like the first, and, like them, always remain wingless. Five or six generations of these parthenogenetic, egg-bearing, wingless mothers follow each other, when (about the middle of June in the latitude of St. Louis) some of the individuals begin to acquire wings. Thus is produced the second or migrating, agamic, winged form. These issue from the ground while yet in the pupa state; as soon as they have acquired wings they rise in the air and spread to new vineyards, where they lay their eggs usually in the down of the under sides of the leaves. Each individual of this generation lays from three to five, and some as many as eight eggs. These eggs are of two sizes; the smaller, which produce males, are about three fourths of the size of the larger, which produce females. From these eggs are hatched in the course of a fortnight the third or wingless sexual form. It is a very remarkable fact that this form emerges from the egg not as larva, but as fully developed individuals. These sexual individuals are born for no other purpose than the production of their kind, and are without means of flight or taking food. After pairing, the body of the female enlarges somewhat, and she is soon delivered of a solitary egg. The impregnated egg gives birth to a young louse, which develops into the first form, and thus recommences the cycle of changes. It has been discovered that sometimes the first form during the latter part of the season lays a few eggs, which are of two sizes like those of the second form, and also produces males and females, which are precisely like those born of the winged form, and, like them, produce the solitary impregnated egg. Thus the fact is established that even the winged form is not essential to the perpetuation of the species. Occasionally individuals abandon their normal underground habit and form galls upon the leaves of certain varieties of grape-vine. Owing to the great injury this species has done to the vineyards of France, hundreds of memoirs have been published regarding it. But as yet no satisfactory means of destroying it has been discovered. The difficulty lies in the fact that the insecticide must be one that can penetrate the ground to the depth of three or four feet, reaching all the fibrous roots infested by the insect. It must be a substance that can be cheaply applied on a large scale and that will kill the insect without injury to the vine. Where the vineyards are so situated that they can be submerged with water for a period of at least forty days during winter, the insect can be drowned. It is found that vines growing in very sandy soil resist the attacks of the grape *Phylloxera*. This is supposed to be due to the difficulty experienced by the insect in finding passages through such soil."

Here we have the whole natural history of a bacillary tubercular disease in plants. Notwithstanding the fact that every phase of its life history is well understood and the diseased parts can be seen and handled, yet its treatment is futile. This teaches us the narrowness of our

* From Dr. C. V. Riley, *Missouri Entom. Rep.*, vi, vii.

† *Microbes, Ferments, and Molds.* By E. L. Trouessart. D. Appleton & Co., New York, 1886.

study of human tuberculosis when we imagine that Koch's discovery of the bacillus placed us in a position to treat this complicated disease. We do not know the manner in which the bacillus gains the position it occupies in the tubercular mass, or why it sometimes attacks the lungs, and sometimes the glands, and sometimes the bones. Is it conveyed to its position by a host? Nothing we as yet know indicates this supposition except the analogy of vegetable parasites. It is not found in the blood or in the muscular juices. The present exclusive devotion to the observation of bacteria would almost preclude the detection of a host if one did exist. Crookshank, in an appendix to his work on *Bacteriology*, says: "When examining blood, the bacteriologist must be prepared to meet with minute organisms, which at the first glance under moderate amplification may be mistaken for vibrionic or spiral forms of bacteria. The organisms referred to belong not to the vegetable but to the animal kingdom. They may occur associated with disease, but they appear to be more commonly found in the blood of apparently perfectly healthy animals." Thus the fact is stated by good authority that parasitic animals do exist in the blood.

This is not the only parasite to illustrate the mimicry of animal and vegetable morbid forms. There are myriads of parasites, and parasites on parasites, in the descending scale to the minutest forms. Thus all vital activity is kept in unison; nothing is allowed to die; one living organism ceases that others may continue, and the others in turn are dissolved to continue other phases of vital activity. The little germ that robs man of his vitality undoubtedly conveys that vitality to some other living organism, thus forming a link in the endless chain of organisms in action.

Another form of change not parasitic is suggestively analogous to the bacillary tubercular phenomena. The yeast plant is a germ, and undoubtedly Pasteur's noted researches on the life history of this plant formed the starting point for the universal study of bacteriology to-day. No thinking man could have followed his reasonings, conclusions, and deductions without concluding that all febrile conditions at least were the result of the growth of germ-life, producing ptomaines, extractives, etc. There are many phases of alcoholic fermentation that mimic the morbid processes of bacillary phthisis.

Thus we know that the presence of the tubercular germ in the mouth or other parts of the body is not always followed by tuberculosis. Analogously we know that the presence of yeast germs in a saccharine solution does not always give rise to alcoholic fermentation. The solution must contain less than twenty per cent. of the saccharine material. Thus the specific gravity of the solution is the controlling condition in the activity of the yeast plant. The same may be true of the human body. It can easily be understood that in the human body the specific gravity may vary. Thus an exceedingly fat and juicy body would be of lighter specific gravity than a closely-knit, hard, muscular body, and undoubtedly the specific gravity of the body has something to do with the morbid action of many of the germ phases of disease. Nor is this all. Before Pasteur's enlightening investigations it was supposed that the yeast germ was contained in the atmospheric dust, but Pasteur proved conclusively that this was not the case. He admitted atmospheric air and its dust into sterilized tubes of proper saccharine solutions for the growth of yeast, but the alcoholic fermentation was never set up in solutions thus treated. Then the question arose, Where did the yeast plant come from? and further study revealed the fact that all kinds of fruit contained on their surface a germ termed by Engel "apiculated ferment" (carpozyma). This is a hibernating germ, and, unless the fruit is bruised and its containing sugar in due proportion brought into contact, the germ will not grow or produce its special changes. This plant does not in any way resemble the ordinary yeast plant unless it is modified by its growth in a fermenting fluid. May we not then easily suppose that some germ-forms exist normally in the animal tissues prone to tubercular diseases, and only develop into the forms in which we find them when some anterior morbid process has been developed? This idea is concisely expressed in a paper read before the New York Medical Association, March 17, 1890, by Dr. James R. Leaming, a gentleman who has grown old in the study of this disease. He says: "I have seen no case of phthisis that could not be accounted for satisfactorily without supposing infection or contagion. I can say more. I have seen no case of phthisis where there was a probability of primary infection with no other cause.

"The first physical evidence of dead atoms in the system is their extension from the capillaries into the pleural cavities, as damaged leucocytes or ptomaines by physical diagnosis; and this may be done before the presence of the bacilli can be detected in the sputa. The bacillus is consequent, not causative; it is true that ptomaines are in the blood before the expression of the leucocytes, but, as a rule, not in abundance sufficient to attract the germs."

This explanation of one phase in the development of tubercular disease will coincide exactly with the development of alcoholic fermentation in the case of grapes. Thus on the surface or in connection with the grape is a hibernating germ, and this germ is never brought into activity unless the grape is bruised and forms a solution, when the germ becomes active and changes the sugar into alcohol and other products of fermentation, which mimic the formation of ptomaines in the animal economy.

There are many other forms of vital processes outside of the animal body that mimic its morbid processes. All these forms are complicated, many of them mysterious, and associated with an interminable train of anterior and subsequent evolutions to the germ activity. My object in alluding to those enumerated is only to show the apparent fallacy of our imagining that because we have discovered the presence of a minute germ, we are also in possession of sufficient knowledge of the morbid processes associated with this germ to indicate a rational mode of treating the disease where the germ exists, without knowing definitely how much other conditions outside the germ have to do with the process. It has ever been one of the characteristics of scientific men to make sweeping and hasty deductions from the discovery of some one undoubted fact. I do not in any manner wish to detract from the honor and brilliancy of Koch's

discovery, but I wish to protest against the tendency of the medical mind to-day to hang everything on the bacillus. For instance, if the bacillus was the only cause of tuberculosis, it would have to be viewed in the light of a foreign body within the tissues, and we know that foreign bodies always set up inflammatory action and subsequent suppuration, which is not always the history of tubercular processes. These are sometimes organized or cretefied. There is a germ disease where the morbid processes depend on the germ and the germ alone, and an abscess is always formed by this germ (actinomycosis), and a cleaning out of the abscess and total elimination of the germ cures the morbid process. But I think the presence of the tubercular bacilli must be viewed in somewhat the same light as the nut-gall of *Phylloxera*. In this the presence of the eggs is not the cause of the tubercular growth, because if the egg alone were deposited in the leaf it would act as a foreign body; it is the material that is injected into the leaf at the same time as the egg is deposited which sets up such an action in the nutritive processes of the leaf that the irritation of the egg is entirely overcome.

Without much stretch of the imagination we can imagine the giant cell as occupying the position in the tubercle of human phthisis that the egg of the *Cynips* occupies in the nut-gall. According to this view, the bacillus would be the nutritive material causing the growth of the tubercle. These surmises and similes could be carried on *ad infinitum*, but I think the mimicry is suggestive enough to indicate to us that there is vastly more to be known of human tuberculosis than merely that a germ is present in a mass of morbid material.

Correspondence.

LETTER FROM DUBLIN.

Dublin Hospital Sunday.—The Royal Academy of Medicine in Ireland.—The Royal University of Ireland.—Professor Koch's Treatment of Tuberculosis.—Typhoid Fever in Dublin.—The Royal Hospital for Incurables.—Sir J. T. Banks, K. C. B.

DUBLIN, *November 25, 1890.*

COLLECTIONS in aid of the Dublin hospitals took place on the 8th inst. in about two hundred and thirty churches in the Dublin district. Last year the Dublin Hospital Sunday Fund obtained a sum of £4,155 5*s*. 4*d*., and since its institution the total collected has amounted to no less than £61,345 15*s*. 9*d*.

The eighth annual general meeting of the Royal Academy of Medicine in Ireland took place at the close of last month, when the office-bearers for the ensuing year were elected. The same evening the Academy lecture, on The Modern Diagnosis of Diseases of the Stomach, was delivered at the Royal College of Physicians by Professor Purser, the chair being occupied by Dr. Samuel Gordon, president of the Academy. Professor Purser, in the course of his address, dealt with the aids which modern research has given to obtaining a better insight as regards the functions of the stomach, both in health and in disease. He recommended the removal of the contents of the stomach with a soft-rubber tube, and then their examination by chemical means to see if free hydrochloric acid was present. He showed that this method was of great practical importance, and enabled the physician in some difficult cases to arrive at a more certain diagnosis than had hitherto been possible. The first meeting of the Surgical Section of the Academy was held on the 14th inst., when an interesting discussion took place on a case of enterectomy described by Mr. Hayes. The varieties of sutures used were referred to, great praise being accorded to the method of decalcified bone plates as suggested by Professor Senn, of Milwaukee. At the termination of the meeting Mr. Croly, the president of the college and of the Section, entertained over a hundred guests at supper at the College of Surgeons.

The degrees recently obtained by the graduates of the Royal University of Ireland were conferred by the Right Hon. J. Ball, LL. D., pro-vice-chancellor, who in the course of an interesting address referred to the fact that female students were in that university permitted to compete for prizes. In every department, he said, they had obtained honors—classics, modern languages, literature, mental and moral science, and even mathematics and the kindred sciences. Miss Robertson had won in experimental physics the highest prize—a studentship of £100 a year, tenable for three years. In the evening a *conversazione*, given by the graduates, took place in the university buildings, and was a great success. It was the first of its kind, and probably will be repeated.

Professor Koch's treatment of tubercle has attracted considerable attention, and several of our physicians and surgeons have gone to Berlin to see the treatment carried out and to obtain the "lymph" necessary for the hypodermic injections. The composition of the fluid has not up to this been disclosed, but it is probable that, if the results are fairly successful, the method of preparation will shortly be published.

Typhoid fever has been rather prevalent for some time past in Dublin, and numerous deaths have taken place from this disease. As the water is one of the purest, the prevalence of the fever is probably due to defective drainage. On the other hand, typhus fever has to a great extent disappeared, although some years since it was one of the most fatal of the zymotic class of affections.

The Royal Hospital for Incurables has been left the handsome sum of £10,000 by the late Mr. T. E. Ryan, of Dublin, one of the governors, who when alive took considerable interest in the working of the hospital.

Sir J. T. Banks, K. C. B., M. D., the eminent Dublin physician, will hold the office of high sheriff for the County Monaghan for next year.

Albuminuria in Infancy.—The *Lancet* for November 15th quotes Seyournet in regard to a newly recognized type of renal congestion, with albuminuria, in very young children, which he believes is not infrequent. It is not the same as scarlatinal albuminuria. He has studied the malady in children from a year to a year and a half old. Many of the subjects were bottle-fed or had been given unsuitable articles of diet, which caused distended stomach and intestines, with catarrh of the latter, sometimes with vomiting and diarrhœa, and in a few instances an enlargement of the liver. He believes that the albuminuria is toxic and due to the generation of certain substances by fermentative action of an abnormal nature within the bowels, and their absorption thence into the renal circulation, the brunt of their offense being expended upon the latter organs. The disease was marked by anuria in many cases; in some cases not more than half an ounce of urine was passed in a day. Œdema of the feet, and even of the face and eyelids, frequently occurred. The duration of the disease was from two to four weeks. The treatment that served the most useful purposes included the employment of intestinal antisepsis, salicylate of bismuth and its congeners being commonly employed, and a diet of milk and lime-water. Gentle aperients were used when there was vomiting, and systematic massage over the kidneys in order to reduce the congestion of those organs.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, DECEMBER 20, 1890.

THE PROGRESS OF THE KOCH TREATMENT OF TUBERCULAR DISEASE.

It appears now that New Haven was not the scene of the first trials of Professor Koch's remedy in America; it had been in use for several days at the Hospital for the Ruptured and Crippled, and it is now the subject of experiment at many of the New York hospitals. So far as inferences may be drawn from what has been observed here and elsewhere, they are suggestive rather than decisive, and they bear more upon the physiological action of the remedy than upon the radical question of whether or not it is curative. We shall revert to these matters farther on. In the mean time mention should be made of a remarkable contribution that has been made to the literature of the subject.*

The work to which we allude is a brochure of fifty-eight pages, by two London gentlemen, and they state that its contents are the outcome of their personal observations in Berlin, chiefly at the Charité. The preface is dated November 29th, and the book shows a number of signs of haste in its preparation, the most noticeable of which is a blank space where there should be an engraving. Mr. Grün and Mr. Severn seem to have been the first to get out a monograph on the Koch treatment, and the gratification of having done so will no doubt compensate them for any chagrin they might feel on account of the defects incident to its hasty preparation. They are enthusiastic believers in the efficacy of Koch's treatment, and they rank his supposed discovery far above Jenner's, classing the latter (somewhat unjustly, we think) as "purely accidental."

They conjecture that the active principle of the Koch liquid is a ptomaine produced by the *Bacillus tuberculosis*, which, they say, is "killed by an excess of its own poisonous excreta." Two engravings are inserted to show the effect of the injection on the microscopical appearance of the bacilli in the sputa. The authors seem, therefore, to believe, contrary to Koch himself, that the remedy acts on the bacilli; and they explain its action as that of an "overtaking treatment" (*Nachimpfung*), denying its analogy to the operation of Pasteur's inoculations with attenuated virus. This theory can hardly be either accepted or rejected without reserve until we have positive information as to the nature of Koch's liquid—information which, as we have before remarked, ought not to be delayed much longer.

Elsewhere in this issue we print some extracts from this very interesting pamphlet. The work contains a goodly number of detailed histories of cases, with particularly full temperature records, although the authors state that they found it impossible to induce the hospital officials in Berlin to have the patients' temperature observed at night.

Several deaths have occurred in Berlin and elsewhere as the apparent result of the injections, and this has emphasized the necessity of caution in their employment. A cable dispatch received on Monday, the 15th inst., from Dr. John Guiteras, of Philadelphia, who is now in Berlin, is summarized as follows in a supplement to the December number of the *University Medical Magazine*, of Philadelphia: "A greater degree of caution is being observed, especially as to the selection of cases of pulmonary phthisis subjected to the lymph treatment. The results, in this disease at least, are as yet inconclusive. Many cases are not decidedly improved. There is some risk of complication. Both pneumonia and meningitis have been observed. The general situation may be summed up by stating that a spirit of caution prevails in Berlin to-day." A press dispatch from St. Petersburg, dated the 17th inst., states that the use of the method in Russia has been prohibited until it has been properly investigated under the direction of the Government. A death has occurred in New York within a few hours after an injection, but it was that of a child almost moribund with tubercular meningitis, and the procedure is not thought to have hastened the death.

Swelling of the spleen and pain in the region of that organ are said to have accompanied the febrile reaction in some of the New York experiments, but Dr. Gibney, of the Hospital for the Ruptured and Crippled, and Dr. Kinnicutt, of St. Luke's Hospital, say that those phenomena have not occurred in the patients under their observation.

In cases of pulmonary tuberculosis, the cough and expectoration are usually increased, and this increase is one of the primary results of the injection, and hæmoptysis is apt to occur. In one of Dr. Gibney's patients, a child whose lungs had been pronounced sound by Dr. Thacher, cough or "snuffles" came on in nine hours after the injection. If this should prove to be a common occurrence, there may be some ground for entertaining the idea that the remedy has an affinity for the pulmonary tract independently of its supposed affinity for tuberculous tissue; but there are some excellent observers who, like Dr. Kinnicutt, do not believe that an individual affected with a tuberculous disease can be said to be absolutely free from pulmonary tuberculosis, although the deposit may be so small that no physical examination, however carefully made, will reveal it.

Lupus seems still to constitute the most favorable field for experiment. No definitive cure of that disease by the new treatment has, so far as our information goes, yet been recorded; but the various observers here and abroad are substantially unanimous in their descriptions of the local and constitutional results of the injections—the affected part becomes swollen, red, and painful, and eczematous exudation follows, this is suc-

* *Handbook to* [*sic*] *Dr. Koch's Treatment in Tubercular Disease.* By Edward F. Grün, M. R. C. S., L. R. C. P., and Walter D. Severn, Assoc. Roy. Coll. Sci. London: J. & A. Churchill.

ceeded by incrustation, and, when the crust falls or is detached, the surface shows decided improvement. The University of Pennsylvania's commission, consisting of Dr. William Pepper, Dr. James Tyson, Dr. J. William White, and Dr. John H. Musser, cite Nencki and Sahli as having shown that the local changes are very similar to those produced by the inoculation of lupous patients with erysipelas; and this suggests that the products of more than one micro-organism—in other words, more than one medicinal agent—may prove antagonistic to the tuberculous processes.

In conclusion, the main question of the curative efficacy of the Koch liquid seems hardly nearer a solution than at first, but our stock of facts in regard to its effects is accumulating satisfactorily.

THE ABUSE OF MEDICAL CHARITY.

We are glad to see so strong and able a protest against the abuse of medical charity in our large cities as that of Dr. Gould, published in the *Medical News* for the 22d ultimo. Evidently he has spent much more thought on this subject than most of us, who, while bemoaning the medical beggary that exists, continue to degrade ourselves and our patients by indiscriminate medical almsgiving, for he has suggested a means, if not of cure, at least of propbylaxis. His statements would seem to be the embodiment of exaggeration to one not acquainted with the actual state of things in our large cities, but the worst of the paper is that it so accurately portrays the truth. Every physician of a clinic can cite cases from his own experience which are evidences of the pauperization of people able to pay him a fair price for his services. The case of curvature of the spine in a person who made the rounds of several hospitals and was given salicylates for probable muscular rheumatism, until finally examined by a more conscientious physician, may be an extreme and humiliating example of careless snap diagnosis and routine treatment induced by the hurry of the clinic room; but we fear that similar cases are only too common, and we know that habits of haste and carelessness are engendered thereby.

Regarding the effect of this abuse upon the young practitioners, Dr. Gould says: "When they enter upon their career they find that the older physicians treat, free of charge, thousands and hundreds of thousands of patients who could pay something, and that the younger physicians who need encouragement and practice, and to whom these patients would naturally fall, are left to starve for years, until somehow they wriggle into a properly compensated practice. It is brutally unjust to the young practitioner." The truth of this needs no affirmation to one who is or has been a young practitioner in a large city.

This abuse, he maintains, has arisen as the combined result of several confluent causes, pre-eminent among which, be it ever remembered, are the tender solicitude and unselfish kindness toward the sick on the part of medical men generally. Prominent among the other causes are the carelessness of almsgivers and testators in not providing against a misuse of their bounty, the neglect of trustees and managers of hospitals to cause a proper investigation of the alleged poverty of applicants for the benefits of the charity, the foolish competition among hospitals to treat the largest number of patients, the desire for clinical material for teaching purposes, the desire on the part of the visiting physician to see many patients in order to study disease in its infinite diversity and gain perfected technique, and, most active perhaps, the desire on the part of the chief and assistant physicians to build up a private practice indirectly.

The results Dr. Gould partially enumerates as: 1. The encouragement of panperism, dependence, and deceit in a large class of the community. 2. The danger that, if it is ignored until it becomes still further exaggerated, when the knowledge of its enormity finally bursts upon the community, all forms of praiseworthy and necessary charity will suffer. 3. Injury to both physician and patient from a hurried and routine diagnosis and treatment. 4. The degradation of the medical profession by encouraging envy and subtle methods of advertising and by depriving the younger members of their proper *clientèle*.

The remedy he suggests is that a codicil to all wills and bequests be prescribed, worded in such a manner that, unless the trustees of the institutions named exercise stringent care that only truly needy persons receive the benefit of the bounty, the bequests shall revert to the heirs. The practicability of this proposition we do not care to discuss at this time, but we are glad to have a definite suggestion made, and if it is practicable its efficiency can hardly be doubted.

We can not agree to all that Dr. Gould says regarding the sufferings of the country practitioner from this cause, for we have known of too many cases in which the country practitioner has caused imposition and deceit to be practiced upon his city brother by advising his patient to attend the clinic, poorly dressed, and to get the benefit of a consultation for nothing. If such patients should thereafter choose to attend the clinic to the pecuniary loss of the practitioner who gave such advice, the latter would suffer poetic retributive justice. But as to the main points in his paper we heartily agree with him. The same effective inquiry that has been found necessary in all other forms of charity should be insisted on regarding the fitness of applicants to receive medical charity, and the rights of the younger members of the profession should be regarded.

MINOR PARAGRAPHS.

THE ABORTIVE TREATMENT OF ERYSIPELAS.

In the *Gazzetta degli ospitali* for October 22, 1890, Dr. Natale Amici adds some remarks to those first published by him in 1885 upon this subject. His method of treatment consists in destroying the streptococcus of erysipelas in the shortest possible time. He insists that the infection is not always limited by the border of the erysipelatous blush, but often extends beyond this into the apparently sound skin, even to a distance of 40 centimetres. This *latent* erysipelas should be treated as well as that which is visible, and herein lies the success of his meth-

od. The chief symptom of latent infection is tenderness on pressure in the apparently healthy skin contiguous to that which is already red and inflamed. Amici has succeeded best with carbolic acid and corrosive sublimate. In using carbolic acid, he formerly combined it with alcohol, taking equal parts of each. This application was effective, but caused smarting and discoloration of the skin. He has therefore replaced the alcohol with glycerin, the proportions remaining the same. The mixture is to be applied every two hours over the whole of the affected parts, and its use continued so long as there are any symptoms of extension of the infection. With persons with a very delicate skin, or with children, the intervals may be made longer. Under this treatment all symptoms of erysipelas disappear within two or three days. Should the subcutaneous tissues be involved (phlegmonous erysipelas), hypodermic injections of a 1-, 2-, or 3-per-cent. aqueous solution of carbolic acid are to be made with a Pravaz's syringe, according to Hueter's method. The urine should always be carefully watched, and, should it show too great an absorption of carbolic acid, the applications must be diminished in number or even entirely abandoned. Amici has never seen any bad results when this precaution was observed. Some individuals can not tolerate the odor of carbolic acid. In such cases Amici employs a 1-per-cent. solution of corrosive sublimate in glycerin, to be used in the same manner. The patient's gums should be carefully observed, to avoid mercurial stomatitis.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

This *Annual Report for the Year ending June 30, 1890*, shows that 32,886 cases were under treatment, the rate of admission to sick report being 1,315·02 to the thousand of strength, 44·12 men to the thousand being constantly non-effective from sickness, and the death rate being 6·33. The volume contains the usual reports on the health of the military departments and on that of the individual posts, on the prevalence of special diseases, on field operations, and on the general sanitary condition of the army. The medical officers of the national guards of the various States may find Captain Brechemin's criticisms on this arm of the militia interesting, and his advice as to a more careful study of certain text-books should be followed. The publication of special reports of medical and surgical cases has been omitted; this seems advisable, for reports of interesting cases should have wider dissemination than the necessarily limited circulation of an official report affords, and such papers unnecessarily increase the bulk of the volume. The efficiency of the medical corps of the army is in no way better shown than by the very nearly constant annual average of the sanitary statistics, and there is every reason to believe that its high standard of excellence will continue.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE NAVY.

During the fiscal year ending June 30, 1890, 12,029 patients were treated, and 9·89 in a 1,000 died; of 13,444 persons examined for enlistment, more than a third were rejected. The Museum of Hygiene at Washington has improved satisfactorily during the year, and its field of usefulness is constantly becoming better appreciated. Reference is made to the failure of Congress to enact a bill for improving the rank and pay of assistant surgeons, and it seems impossible to obtain a sufficient number of qualified physicians to fill existing vacancies. The volume concludes with the usual statistical tables and reports of medical officers attached to the different vessels.

SALICYLIC ACID AS A PROPHYLACTIC OF SCARLET FEVER.

In an October number of the *Centralblatt für klinische Medicin* Dr. G. Sticker reports the observations of Dr. G. de Rosa, as published in the *Giornale internazionale delle scienze mediche*, as to the value of salicylic acid as a preventive of scarlet fever. Out of sixty-six children exposed to the infection, twenty-seven cases existing in one house, only three took the disease after the administration of the drug, and in those the failure was attributed to the fact that its administration had been begun too long after exposure. Its use is to be begun when there is danger of infection, giving from 0·1 to 0·3 gramme (1·5 to 4·5 grains) daily, until the possibility of infection is past. It is not necessary to isolate the patients, for fear of their communicating the disease, under this *régime*.

EUPHORINE.

The name euphorine has been suggested by Professor Giacosa for phenylurethrane, $CO\begin{matrix}OC_2H_5\\NH(C_6H_5)\end{matrix}$, a compound resulting from the action of ethyl ether on aniline. It is a white crystalline powder, with a faint aromatic odor and a slight taste, almost insoluble in water, but soluble in weak alcohol. Dr. Sansoni, of Turin, in the *Therapeutische Monatshefte* for September, as mentioned in the *Internationale klinische Rundschau* for November 2d, gives the result of a number of observations on the action of euphorine in disease. Summing up the results of such investigation, the antipyretic, antirrheumatic, and analgesic actions seem, he says, to be inferior to those of many of the better-known remedies of the same group.

THE FIRST AUTOPSY IN NEW ENGLAND.

The *Boston Medical and Surgical Journal* has a note regarding the first post-mortem performed in New England. It recounts the pathological examination of the body of a child, eight years old, Elizabeth Kelly by name, who died in March, 1662, at or near Hartford. The child undoubtedly died of some acute disease, but there was a charge of witchcraft about it, the death being imputed to the malign influences of the gudewife Ayers, as a witch. This good lady and her husband were compelled to flee from their home lest they be made to suffer the penalty of the charge, which was hanging. They left behind them a child, who became the ancestor of one of the present families of Hartford. This event was recently brought to light by Mr. C. J. Hoadley, librarian of the State Library of Connecticut, and made the basis of a paper read by him before the Hartford County Medical Society.

MENTHOL FOR CHAPPED HANDS.

A writer in the *Provincial Medical Journal* offers the following: Menthol, 15 grains; salol, ½ drachm; olive oil, ½ drachm; lanolin, 1½ ounce, as a soothing application for chapped hands. The pain, he says, is at once allayed after the first application and the skin at the same time is softened. The fissures will heal promptly under a systematic use of the application once or twice daily.

CHLOROFORM OINTMENT.

Kittel, according to the *Druggists' Circular*, recommends the use of chloroform externally in the form of an ointment. For this purpose he prescribes one part of chloroform, one part of wax, and two or three parts of lard. This mixture will keep the chloroform unaltered, and, when spread upon linen and ap-

plied to the unbroken cutaneous surface, acts quickly and with certainty as a local analgesic. Its mode of preparation is simple: The wax and lard are melted together, and, when somewhat cooled superficially, poured into a bottle, the inside of whose neck as well as its glass stopper have been well greased to make it perfectly air-tight; then the chloroform is stirred in. The bottle must be kept in a cool place until the mixture stiffens, being occasionally rotated without being opened.

A CASE OF VISCERAL NEURITIS.

Dr. John Ferguson, of Toronto, reports in the *Alienist and Neurologist* the case of a woman, aged forty, who had, following an attack of influenza, the most frightful paroxysms of pain, which nothing could allay, and, despite the efforts to relieve her, died after two weeks of great suffering. Examination of the nerves and ganglia throughout the abdomen showed them to be in a highly inflamed state. Microscopically, there was marked degeneration in some of the nerve tissues. The author said that, while peripheral neuritis was a recognized condition, he saw no reason why neuritis might not affect the viscera, and that this cause might account for some of the violently painful and obscure conditions occasionally met with.

TUBERCULOUS ABSCESSES TREATED BY IODOFORM INJECTIONS.

Dr. Bullitt, of Louisville, writing from Bonn to the *American Practitioner*, speaks of the plan of treating tuberculous abscess, now used to a considerable extent in Germany, by the injection of iodoform in olive oil, one part of the former to ten of the latter. A rather large needle is used, and the pus is allowed to escape through the needle before the injection is made; but no great stress is laid on this evacuation of the pus. The injection of the iodoformed oil is then performed, varying in quantity according to the size of the abscess. This is repeated once or twice a week. Marked improvement has seemed to follow this treatment in two classes of cases, one being that of patients suffering from tuberculous testis, and the other, that of those having abscesses in the vicinity of diseased joints.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 16, 1890:

DISEASES.	Week ending Dec. 9.		Week ending Dec. 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus fever	0	0	0	0
Typhoid fever	19	6	15	8
Scarlet fever	77	6	78	4
Cerebro-spinal meningitis	2	1	6	3
Measles	254	15	292	19
Diphtheria	114	35	113	25
Small-pox	0	0	0	0
Varicella	4	0	9	0

Gruen and Severn's Observations of the Koch Treatment in Berlin.—With some verbal changes, the following consists of extracts from a brochure recently issued in London by Mr. Edward F. Grün and Mr. Walter D. Severn:

The Liquid.—The active principle is so excessively powerful in its action that the actual maximum strength of the liquid as at first obtained would be far too great for use; the strongest solution which is actually used in the injections, even in the most extreme cases, is a ten-per-cent. dilution of this "original" liquid with distilled water, to which one per cent. of phenol has been added. The maximum quantity injected in one place is a cubic centimetre.

When the liquid is once diluted, its keeping properties are considerably diminished. Not only is it more subject to chemical change—presumably of the ptomaine in solution undergoing decomposition or rearrangement of the atoms in the molecule—but also it is nearly sure during previous operations to have derived bacterial impurities from the atmosphere or surrounding objects, so that before use each time the solution should be heated to kill any spores of bacteria which may have sprouted in the intervening time. But after a certain number of heatings it is observed that the activity is much diminished, and this is also owing probably to a chemical decomposition or change which goes on, promoted by the repeatedly raised temperature, so that freshly diluted lymph must be prepared every few days. Taken by the mouth, the liquid is absolutely inert; inhaled, it is very powerful, but in this method the dosage is so difficult to control that for purposes of general convenience and scientific accuracy it is in every way better to administer the fluid by means of the hypodermic syringe.

The Injection.—The fluid is of such an intensely active nature, so prone to undergo decomposition through careless manipulation, that almost certainly, unless careful antiseptic precautions are observed, abscesses of excessively severe nature, with or without general pyæmia, or even fatal septicæmia, would result. The antiseptic precautions necessary are the following: First, the syringe must be carefully sterilized; second, the place where the injection is to be made must be washed with absolute alcohol (the hands of the operator after well washing should also be rinsed with absolute alcohol); and, third, the cotton-wool plug in the tube of diluted liquid ought only to be removed for so long a time as will allow a certain quantity to be removed by the syringe, and then quickly replaced. The needle must be cleansed before and after every operation with the silver wire and absolute alcohol. The injection must be made on the opposite side to that on which the patient habitually lies, below the shoulder blade, in the region of the latissimus dorsi; otherwise the subsequent local tenderness interferes considerably with sleep. The injections are preferably made early in the morning; 9 A. M. is the time adopted in Berlin, and would be a good hour at all times. The weakest injections must be begun with a solution of such strength that on injecting a cubic centimetre the patient shall receive 0·001 of the strong original liquid. The temperature must then be observed every four hours, in order that the time when the reaction sets in (usually in six hours) may be observed, and that any other results of this reaction may not escape notice. When no further injection reaction sets in the strength of the solution must be increased, for the reason that, if a strong solution is at first made use of, the reaction is great, but a tolerance is the sooner established and the succeeding treatment produces little or no benefit. This does not, however, apply to lupus cases, where a solution as strong as 0·01 may be begun with at the first trial. In injecting, the needle must be pushed right home, and the fluid slowly forced in and allowed fully two minutes for its total expulsion.

The Effects of the Injection.—The effect of the injection used for the first time is to produce in the course of about three hours, according to the nature of the case, a decided rigor followed by a fairly sudden rise in the temperature, which, as exemplified in a case, rose from 98·2° F. at 3 P. M. to 101·8° at 6 P. M., and at 9 P. M. to 104°—sinking again by morning to 99·2°. If the case presents a local lesion of tuberculous nature, this lesion swells and becomes tender, and the skin over it becomes somewhat inflamed. The patient feels drowsy, disinclined to stir, and nauseated, and loses his appetite for the time being. In cases of advanced phthisis the temperature has risen to 105·8°, fatal collapse has come on, and, the temperature sinking, the patient has died. This has only taken place in cases of very advanced phthisis with cavities. The temperature often becomes subnormal, and it may be stated that the higher the temperature of the reaction the lower will it subsequently fall. An increase in the dose by no means always produces an increased temperature, but it is advisable to begin with the lowest possible dose, otherwise the limit of dosage is soon reached, and the patient becomes tolerant. It does not, however, follow that because the patient becomes tolerant and no reaction follows, the injection ceases to produce benefit, although the physicians treating the cases at present are rather inclined to adopt this view. The rapidity of the pulse rises considerably during the reaction, and often reaches a rate

of 130 or 140 to the minute. Dr. Köhler has reported it as having gone up as high as 160 without failure of the heart's action. Where patients have previously suffered from asthma an attack often sets in during the reaction. Other patients who had not previously suffered from asthma have been troubled with some dyspnœa during the reaction. At a meeting of the Berlin Medical Society on November 20th two cases were shown where a well-marked exanthematous rash appeared over the front of the chest, the legs, and the arms, which rash lasted about two days.

In cases of phthisis, when an injection is made, there are an increase in frequency of the cough, more distress with the same, and a feeling of restlessness and shortness of breath; at first the patient feels undoubtedly worse, and there is occasionally some slight collapse, which, if necessary, must be treated with the free administration of stimulants—in short, the patient must be watched. The intensity of the reaction is in ratio to the stage of the disease; in the advanced cases the reaction is so great as occasionally to produce dangerous symptoms, and these cases must be treated with very dilute solutions to insure perfect safety. When there has been a previous elevation of temperature, what is called a "disease fever" (*Krankheitsfieber*), the reaction rise is marked, and there then follows a fall which includes both the reaction temperature and the disease fever. The sputum becomes much more fluid, loses its yellow color, and diminishes in amount, being at the same time much easier to expectorate. The cough becomes softer and moister. The patient begins to improve in weight. The bacilli undergo an early diminution in numbers and also an alteration of form when seen under the microscope, many slides exhibiting these changes in a marked degree. The special changes are a lessening of the size, a breaking up into *débris*, and a bending into a half-moon shape, some exhibiting a swelling at either end; not only is this noticed in one or two of the specimens on the slide, but the whole slide is in this condition, a healthy, well-developed bacillus being difficult to find —in other words, the bacilli evidently undergo a species of degeneration. Sufficient are probably left, however, to form a fresh nidus of infection if the treatment were discontinued at this stage, and it must be assumed that it will in all cases be necessary to continue the treatment until the sputum is entirely free from bacilli. The influence upon the percussion-note is well marked. In some cases the dullness has been found much diminished in area. The crepitation disappears. The night sweats entirely disappear in most cases after the first fortnight, and this may account for the increase in weight.

The Local Reaction.—In lupus the first effect is to produce within three hours a feeling of burning, tightness, and heat over the face and nose, and at the time of the commencement of the rigor the nose becomes noticeably reddened. In six hours the swelling and redness reach their highest point; they are not confined to the affected part, but implicate the skin for some distance around; at about the same time there is an ample exudation of a yellow fluid similar to that found upon an eczematous surface, which dries into crusts upon the surface. The exudation continues for about forty-eight hours. After two days the redness and swelling begin to subside, and after five days are only apparent upon the affected part, and even this becomes considerably paler during the following three weeks. Five days after the injection the scales begin to dry up and fall off. On the ninth day they may be taken freely off their bases. The affected part now appears quite shrunken, red, and shiny, just as those parts of a lupous patch appear which have been treated with a Volkmann's spoon. After a certain number of days the swelling of the nose subsides, and the organ regains its natural shape and outline; however, a number of small tuberculous spots remain, most of them of about the size of a pin-head, forming a soft red prominence whose center often carries a small scale. These spots, in a case under observation, increased considerably in size before the day of the second injection. The second injection was made twenty-seven days after the first, and repeated three times at intervals of two days. After each injection, redness, swelling, and exudation took place, although not to the same intensity as the first time. At the time when the patient was shown, the swelling and scaling had still not completely finished. In one case exhibited, some tubercles imbedded deep in the skin had so far resisted the treatment, and Dr. Köhler gave it as his opinion that this resistance was due to the thickness of the elastic tissue of this part of the skin preventing the outlet of the exudation to the surface, and thought it highly probable that absorption of the masses would take place. The only example shown in which an absolutely complete cure had been established was that of a woman on whom Volkmann's spoon had been freely applied before injection. This rather spoiled the scientific value of the evidence it supplied. In a case of enlarged tuberculous glands, after injection, swelling and pain took place at the seat of enlargement. At the same time all the enlarged glands were not equally affected; some of the glands became very enlarged and painful; others were not nearly so much, if at all, affected.

Dr. Abbe's Case of Gonorrhœa in a Child.—In the history of this case, published in our last issue, on page 666, the strength of the solution of corrosive sublimate employed as an injection was erroneously stated as 1 to 8,000. It should have been 1 to 80,000.

The Medical Society of the County of Kings held a reception on Friday evening, the 12th inst., at its rooms, in Bridge Street, Brooklyn.

A Public Bath-house is to be built by the New York Association for Improving the Condition of the Poor, on land in Broome Street given for the purpose by the City Mission and Tract Society. It is announced that the house will be built after plans prepared by Dr. Simon Baruch.

The Ravages of Epidemic Influenza.—Dr. Benjamin Lee, secretary of the Pennsylvania State Board of Health, has reported to his board an estimate of the extraordinary losses of life by influenza during the recent epidemic. The number of cases in the State was probably not less than 1,120,000, and the number of deaths was 7,880, or at the rate of one death in every 142 cases.

The Turin Academy of Medicine.—The subject chosen by the Academy for the Ribieri prize is Researches on the Nature and Prophylaxis of the Infectious Diseases of Man. The value of the prize is 18,000 lire, over $3,500. It is open to international competition, but the competing essays are limited to the three languages, Latin, French, and Italian.

Leprosy at Cape Breton.—Two more cases of this disease have been discovered near Lake Ainslie, at Cape Breton. The patients are women who have until quite recently mingled freely with their neighbors. The attention of the Government has been called to the question of the greater or less latency of leprosy among certain families at the Cape, with a view to the isolation of all residents discovered to be leprous.

Changes of Address.—Dr. Peter J. Gibbons, from Pittston, Pa., to No. 324 Warren Street, Syracuse, N. Y.; Dr. H. N. Vineberg, to No. 167 East Sixty-first Street.

The Death of Dr. Glover Perin, of the Army, is announced as having taken place at his home, in St. Paul, Minn., on Monday, the 15th inst. Dr. Perin served in the Mexican War and in the War of the Rebellion, and afterward as a medical director. Three years ago he was retired with the rank of colonel.

The Death of Dr. William N. Hibbard, of Chicago, on October 29th, is thought to have been due to ptomaine poisoning consequent upon the ingestion of oysters. He was one of the junior attachés of the Chicago Medical College, and a young man of brilliant promise.

The Death of Dr. Sidney Allan Fox, of Brooklyn, occurred on December 10th. He was thirty-three years old, a native of Kentucky, a graduate of Bellevue Hospital Medical College, and an ex-interne of Charity Hospital. He had lived in Brooklyn since 1882, and was widely known as a specialist in diseases of the throat and nose. He was largely instrumental in the inauguration of a special hospital for the treatment of those diseases.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 30 to December 13, 1890:*

Swift, Eugene L., First Lieutenant and Assistant Surgeon, is, by direction of the Secretary of War, relieved from further duty and

station at Fort McDowell, Arizona Territory, and assigned to Fort Thomas, Arizona Territory, where he is now on temporary duty. Par. 16, S. O. 282, A. G. O., Washington, December 3, 1890.

Pilcher, James E., Captain and Assistant Surgeon, now on leave of absence, will, by direction of the Secretary of War, report in person to the commanding general, Division of the Atlantic, for temporary duty at Fort Columbus, New York Harbor, during the absence on leave of Captain William E. Hopkins, Assistant Surgeon. Par. 3, S. O. 278, A. G. O., Washington, D. C., November 28, 1890.

Hopkins, William E., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for six months. Par. 2, S. O. 278, A. G. O., Washington, D. C., November 28, 1890.

Taylor, Marcus E., Captain and Assistant Surgeon, is relieved from further duty at Boise Barracks, Idaho, by direction of the Secretary of War, and will proceed, at the expiration of his present sick leave of absence, to Vancouver Barracks, Washington, and report in person to the commanding officer of that post for duty, reporting also, by letter, to the commanding general, Department of the Columbia. Par. 17, S. O. 287, A. G. O., Washington, December 9, 1890.

Gandy, Charles M., Captain and Assistant Surgeon, now on leave of absence, will, by direction of the Secretary of War, report in person, without delay, to Colonel Eugene A. Carr, Sixth Cavalry, at Rapid City, South Dakota, for duty with troops in the field, reporting also, by letter, to the commanding general, Department of Dakota. Par. 14, S. O. 287, A. G. O., Washington, December 9, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending December 13, 1890:*

Atlee, L. W., Assistant Surgeon. Ordered to examination preliminary to promotion.

Martin, H. M., Surgeon. Placed on Retired List, December 4, 1890.

Alfred, A. R., Assistant Surgeon. Ordered to the Naval Hospital, Norfolk, Va.

Whitfield, J. M., Assistant Surgeon. Relieved from duty at the Naval Hospital, Norfolk, and ordered to the U. S. Steamer Chicago.

McCormick, A. M. D., Assistant Surgeon. Detached from the U. S. Steamer Chicago, and to wait orders.

Keeney, J. F., Assistant Surgeon. Ordered to the U. S. Steamer Minnesota.

Harris, H. N. T., Assistant Surgeon. Detached from the U. S. Steamer Minnesota, and wait orders.

Bloodgood, Delavan, Medical Director. Ordered to Charleston, S. C., to represent the medical corps of the U. S. Navy at the meeting of the American Public Health Association.

Ames, H. E., Passed Assistant Surgeon. Ordered as a delegate to Charleston, S. C.

Bertelotte, D. N., Surgeon. Detached from the Naval Hospital, Philadelphia, and ordered to special duty in connection with the World's Columbian Exposition.

Dickson, S. H., Passed Assistant Surgeon. Detached from the Atlanta and granted two months leave of absence.

Wentworth, A. R. Ordered to the U. S. Steamer Atlanta.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the two weeks ending December 6, 1890:*

Fessenden, C. S. D., Surgeon. Leave of absence extended seven days. December 4, 1890.

Bailhache, P. H., Surgeon. Granted leave of absence for twenty days. November 28, 1890.

Hutton, W. H. H., Surgeon. To proceed to Solomon's Island, Md., on special duty. November 29, 1890.

Sawtelle, H. W., Surgeon. Granted leave of absence for ten days. December 2, 1890.

Peckham, C. T., Passed Assistant Surgeon. Granted leave of absence for ten days. December 1, 1890.

Hussey, S. H., Assistant Surgeon. When relieved, to proceed to New Orleans, La., for duty. November 24, 1890.

Groenevelt, J. F., Assistant Surgeon. When relieved, to rejoin station. November 24, 1890.

Cofer, L. E., Assistant Surgeon. Ordered to temporary duty at Boston, Mass. November 24, 1890.

Society Meetings for the Coming Week:

Monday, *December 22d:* Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, *December 23d:* New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society (private); Jenkins Medical Society, Yonkers, N. Y.; Medical Society of the County of Lewis (quarterly), N. Y.

Wednesday, *December 24th:* New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany; Philadelphia County Medical Society.

Thursday, *December 25th:* New York Academy of Medicine (Section in Obstetrics and Gynæcology); New York Orthopædic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Friday, *December 26th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, *December 27th:* New York Medical and Surgical Society (private).

Letters to the Editor.

THE TREATMENT OF ABORTION.

Point Pleasant, N. J., *November 12, 1890.*

To the Editor of the New York Medical Journal:

Sir: In your issue of the 8th inst., page 520, under the head of The Treatment of Abortion, is a communication from Thomas A. Elder, M. D., of Seaton, Ill. In referring to the use of the tampon, as advised by Professor T. Gaillard Thomas, he scores him in these words: "This is no doubt classical and *efficient* and *sufficiently dogmatical.*" I don't understand his use of the word classical, unless he may mean that it is good teaching to give to a class (referring to Dr. Thomas's lectures).

He has *no doubt* of its *efficiency*, and yet he characterizes it as dogmatical. I think the term decidedly misapplied, unless he is so ignorant of Dr. Thomas's methods as to think that he uses and recommends the tampon in all cases without regard to existing conditions, as, for example, that he would apply the tampon when the products of conception were presenting and removable through a dilated os.

He next proceeds to give *his method*, which has not failed in twenty-two years, and which is the removal in *every case* and *immediately* of all the products of conception by the finger introduced into the uterus and, if necessary, the whole hand in the vagina.

I should like to ask which is the most dogmatical. Dr. Thomas gives a method which any one of ordinary deftness can apply successfully in every case if necessary, and of the efficacy of which there is no question, the only objection to it being that it increases the strength of the uterine pains, is difficult of application, and uncomfortable to the patient, all of which, even if true, which they are not, except the increase in efficiency of the uterine pains, would not overbalance the good accomplished by its use.

Dr. Elder gives a method which, notwithstanding his statements, every practitioner of any experience in that line of work knows to be utterly impossible of execution in a great number of cases by the general practitioner, and indeed I believe by any one. Dr. Thomas has probably tried every method that could promise any assistance in such cases during his long and fruitful career, while Dr. Elder professes only to have found necessary the use of this one (his) method during all of his twenty-two years' practice. He is to be envied if such is the case.

After the uterus is emptied he gives half a drachm of Squibb's fluid extract of ergot and directs that twenty drops be given every four hours or oftener, if necessary to control hæmorrhage, for thirty-six or forty-eight hours.

He says, "I next impress upon the mind of the patient the importance of keeping quiet in a bed for a week or ten days, direct her to keep her person and bed scrupulously clean, to keep her bowels open with mild laxatives, to sit on the chamber when passing urine, and to take her accustomed food." He next gives seven reasons in support of *his* method, as follows:

"1. It is sufficiently simple.

"2. It is not very difficult.

"3. I have found no great difficulty in passing the finger into the uterus at the fifth or sixth week of pregnancy.

"4. It is the best method of arresting the hæmorrhage. It ceases or becomes practically harmless as soon as the finger passes the cervix, especially if the finger fits the cervical canal tightly.

"5. It saves the woman the hours of exquisite suffering of uterine contractions, and the pressure of the tampon.

"6. It terminates the case in about the time it would take to make ready the tampon.

"7. In a fair experience of over twenty-two years I have never met with a case in which it failed, or in which there were after-complications"

He says he never has trouble in introducing the whole hand into the vagina or in emptying the uterus afterward. The only way in which I can reconcile his statement with the facts as I find them is by taking it for granted that he lives in a community the moral tone of which is only to be equaled by that of fabled Acadia, and which never has use for, or is disturbed by, certain meddlesome old women or the professional abortionist. Consequently, all his cases have been normal cases, and that his appearance on the scene has been timed with unusual consideration; and, last, but by no means least, that he must be equipped with a perfect gynæcological hand and not have to depend, as some of us unfortunately do, on a broad hand with short, blunt pointed fingers; or else he must have discovered some method of inducing the os to dilate which I am sure the profession at large would be glad to have him explain.

Taking his reasons in order, I would say, so far as my experience goes and from what I can learn from the writings of others—

1. It is not *sufficiently* simple. I may be indextrous or lacking in experience or something, as I have found that when there was any dilating to do, it was usually anything but sufficiently simple.

2. When no dilatation, or very little, is necessary, it *may be not very* difficult. But, again, I have found it extremely difficult and often impossible, and I have found that in these same cases the tampon stopped the flow of blood and quickly brought the case to a safe and successful termination, and without any more pain than was necessary for the dilatation of the os.

3. Nor would any one find it difficult if he found it wide open always.

4. When the os is open or easily dilatable, the vagina large, the subject not very sensitive, it is undoubtedly often comparatively easy to remove the cause of the trouble with the finger. On the other hand, when the os is not soft and open, but is rigid and only open enough to permit a stream of blood to escape, I think every woman will agree with me and prefer to be tamponed with a well fitting tampon made from proper material, rather than with the hand of the physician.

5. If the os is not sufficiently open for the escape of the offending mass or for its easy extraction with the finger, then I believe that, although the os may be comparatively easy of dilatation, so far as actual pain and discomfort are concerned, the tampon is the less disagreeable and offensive to the patient, and certainly there can be no comparison by those who have tried both methods, between attempting to dilate a rigid, undilatable os with the finger and the tampon. There can be but one decision, and that emphatically in favor of the tampon.

6. If the doctor should not go prepared for all emergencies, he might be able to stop the flow by a tampon composed of a finger in the cervical canal and the hand in the vagina a little quicker than with the regulation material, but, to transpose an old saying, "to take the shortest road is not always the quickest way to get to a certain point," and it might be so in this case. The os might not be open or dilatable, and it would be unpleasant, to say the least, to all concerned to leave such a tampon in place long enough to do any good; consequently it would have to be removed and other proper measures used, either rapid instrumental dilatation or the tampon. Time would have been lost and the patient subjected to unnecessary pain and annoyance.

Before the introduction of the tampon I doubt not many of us were nearly at our wits' end many times. It is certain that we now frequently meet with cases which are wholly uncontrollable (so far as we are concerned) by the doctor's method.

I think I can speak for many brother practitioners when I say we should be only too happy if we might have so fair an experience; but, alas! it is not so.

Taken altogether, the treatment of abortion is one of the most unpleasant and unprofitable of the duties of our profession, as its successful treatment too often brings a reputation the reverse of enviable. One other point. As it takes longer for the uterus to undergo subinvolution than at term, his time is rather short and should be two or three weeks.

The rest of his treatment is not to be complained of in an uncomplicated case, but I am sure that he would be pleased with the results if he would continue small doses of ergot three times a day for three or four weeks.

I have not had so long or so fair an experience as the doctor, but what I have had tends to convince me that there is no royal road by which an abortion may always be conducted to a successful termination. At the same time, I believe the systematic use of the tampon to be as near as it is possible to get to such a method. I believe that in those cases where the doctor is compelled to dilate, it could be accomplished quicker, easier, and with less pain, discomfort, and embarrassment to the patient, by the use of instrumental dilatation with the aid of a few drops of chloroform, and also that there would be less danger of after-complications.

To sum up briefly, I would say:

1. In those cases where the os is within reach and is dilated, and the contents of the uterus are protruding, undoubtedly the thing to do is to remove the mass as speedily as possible with the finger or otherwise.

2. When the os is dilated, but not enough and soft, the best method is instrumental dilatation and removal.

3. When the os is not dilated, but rigid, and is giving forth a stream of blood more or less regular and large, unless there is

some special reason for haste when instrumental dilatation may be advisable, the tampon is *the* remedy for the arrest of the hæmorrhage, and also for the safe and rapid dilatation of the os and expulsion of the offending mass.

F. Whitaker, M. D.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twelfth Annual Congress, held at Baltimore, on Thursday, Friday, and Saturday, May 29, 30, and 31, 1890.

The President, Dr. John N. Mackenzie, of Baltimore, in the Chair.

(*Continued from page 363.*)

A New Operation for Deviation of the Nasal Septum, with Report of Cases.—Dr. Morris J. Asch, of New York, read a paper on this subject. (See page 675.)

Dr. J. C. Mulhall said: I am very much interested in this subject, for one reason at least, because we have in our city (St. Louis) the gentleman who first introduced the instrument which is generally used for overcoming the resiliency of a deviated septum. I refer to Dr. Steele, the inventor of Steele's forceps. I have performed a number of operations, some fifteen or twenty, with this instrument, and I may say that I have not been entirely pleased with it. I am therefore much interested in Dr. Asch's operation, which promises so much from a single incision of the septum; while Dr. Steele's forceps makes six incisions. One objection to the latter is that at the center of the crucial incisions a perforation not infrequently results, upon which crusts form, to the great annoyance of the patient. In maintaining the septum in position after operation, I have found nothing answer the purpose so well as a small rubber nipple, adapted to the size of the nostril and stuffed with cotton, so as to accommodate it to the cavity. This is the best plug to retain the septum in proper place. With regard to the recurrence of the stenosis, I may say that I have been uniformly successful in establishing breathing through the stenosed side by this method.

Dr. Jarvis: The remark with regard to the occurrence of perforation leads me to say that, some time since, I constructed a modification of Steele's forceps which makes six radiating incisions, but leaves an uncut island in the center, thus avoiding the accident just referred to. I have not published a description of the instrument, but it is figured in Reynders's catalogue. In this connection I might call attention to a suggestion concerning the after-treatment. Finding that plugs of hard rubber, glass, ivory, or gauze gave rise to pain and irritation, I have abandoned all internal splints and devised an external nasal splint, coated with very soft leather, or a soft kid pad containing metallic mercury, which have given just as good results without intranasal irritation.

Dr. Ingals: The operation proposed by Dr. Asch is not new, but is a modification of the usual plan of treatment. The late Professor Moses Gunn, of Chicago, was accustomed to make a crucial incision through the greatest convexity of the cartilaginous septum, making the incisions obliquely, and then forcing over the segments and retaining them by means of a rubber tube passed through the obstructed side. When the septum is bent nearly horizontally across the naris, I still prefer the removal of a triangular piece, so as to allow it to fall into proper position, as recommended in my paper read at the Boston meeting of this association. When there is simple bending, with little or no hypertrophy, I use a small trephine, 3 mm. in diameter, with which I remove beneath the mucous membrane three or four cylindrical pieces from the convex portion of the septum, sufficient to completely destroy its resiliency. It is then comparatively easy to place the septum in its normal position and keep it there with some kind of splint. My own custom is to introduce into the nasal chamber of the affected side a pledget made with a long strip of antiseptic gauze saturated with a thick mixture of tannin and water. The other nostril is left open. Twenty-four hours afterward I have the pledget removed, and then cleanse the nose and insert a tube made of gutta-percha, molded to fit the cavity. This should not be large enough to cause the patient discomfort. I use the ordinary sheet gutta-percha employed by dentists, which may be easily molded when warm to suit the requirements of each case. It has proved to me more satisfactory than either ivory, soft rubber, or any of the rigid clamps, and it is infinitely superior to cotton, which not only fails to keep the septum in proper position, but speedily becomes offensive.

Dr. Roe: This method seems more particularly directed to the cartilaginous septum. A somewhat similar plan which I have followed is to make an incision on the convex side in the direction of the greatest convexity, either vertical or diagonal. Then, taking an Adams's forceps, I bend the septum forcibly over to the opposite side until, when left to itself, it keeps a perfectly straight position. Upon the side of the convexity is placed a plug, consisting of metal covered with absorbent cotton. After all hæmorrhage has been checked, I thoroughly disinfect with iodoform, and then introduce a plug as large as can possibly be put into the nostril, adding sufficient absorbent cotton to keep it in place. No plug is placed on the opposite side. The plug should be as wide as the nostril will permit, and, by dipping it in a 1-to-2,000 solution of bichloride of mercury, it is kept thoroughly aseptic. It may be left in position for from four to six days; if necessary to renew it, the same method is followed. When there is deviation also in the bony septum, I break that up with a forceps, and afterward keep the septum in place in the manner described. I have found that these soft plugs are far better than the hard ones, either of rubber or of metal, which are very apt to cause destruction of the mucous membrane by pressure. In the cases of deviation of the bony septum there is almost always an ecchondrosis or an exostosis on the convex side, which must be removed. For this I generally use the nasal saw, so that the septum is of the normal thickness before attempting to restore it to its normal position.

The President: With reference to the principle of this operation, it is of course old. As I showed in a communication presented some years ago, it was first suggested by Bolton, of Richmond. Dr. Bosworth gives Chassaignac the honor, although I can not see why he should. With regard to Steele's forceps, I have used it a good many times and have not been satisfied with it. I find that it does not cut through the septum. The only forceps made on that plan that I use is that made by Gemrig, of Philadelphia, which is called Steele's forceps, but is really a modification of the original. This is the only really practical instrument I have ever used. I invented an instrument myself which cut through the septum, but it was very difficult to get out of the nose, especially where the patient was a little unruly; I afterward discarded it for the instrument made by Gemrig.

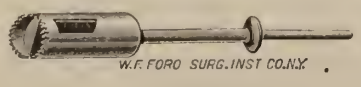
This class of cases is one of much interest. In some you will operate, and in the course of a few months the patients return in just as bad condition as before. Therefore any operation which promises the restoration of the septum to the median

line should be well received and carefully tried. Dr. Asch's paper is very well timed and his method is worthy of trial.

With regard to Dr. Jarvis's external nasal splint, I am sorry to make an unfavorable report. It has not proved satisfactory in my experience. The plug seems necessary, and yet I have comparatively rarely seen a patient who could endure it for six days or more, as some advise. So early as the second day there is profuse secretion, more or less purulent, and the patient begs to have it out. There is no need of plugging both nostrils. I have tried all kinds of plugs, and generally remove them the day after they are introduced. I think that absorbent cotton with glycerin or vaseline is about as good as any you can get for this purpose. In children it is infinitely superior to the ivory plug. I have had one case in which the introduction of an ivory plug caused convulsions of the corresponding side of the body. This phenomenon was repeated several times. On this account I was obliged to abandon the use of the plug, and I recommended in place of it pressure by the little finger inserted into the nostril to push the cartilage over and keep it in the median line. By doing this frequently, the patient obviated the necessity of using the plug. The cutting of the septum is really the smallest part of the treatment; it is necessary to retain the septum in place, and the after-treatment presents the real difficulty, and is often the cause of failure. Orthopædic appliances are of but little value here.

Dr. Langmaid: It does not matter so much how you break down the septum. The problem is analogous to that presented by a case of hare-lip, to prevent the recurrence of the deformity. You may adopt any operation, but the septum must remain in the new position or the operation will be a failure. In order to prevent recurrence. I insist that the operation must have the result of destroying the resiliency of the deviated septum, so that it will, of itself, remain in proper position without being held there by a plug or splint. I must bear testimony to the value of the black rubber-nipple plug stuffed with cotton. In small children a very small plug may be used, and it need not be soft: but in older children it may be filled with cotton and iodoform and answers the purpose very well In addition, the expedient mentioned by the president—of making pressure with the finger—is useful, the patient being instructed how he may aid the treatment by inserting his little finger several times a day. In many cases a purulent discharge is set up, and there may be neuralgia and other nervous symptoms. The size of the nostril should be borne in mind in making the plug so that it will go in easily; as the septum will remain in place, there should be no pressure and no pain or inconvenience.

Dr Jarvis: With regard to the external nasal splint, I would only add that, although I have used it in a number of cases, I have lately discarded it in favor of a new crown drill, which quickly cuts away the septal distortion. I agree with the president that orthopædic appliances are out of place in intranasal surgery. The rule is always to remove sufficient tissue



to give plenty of room. By using transfixion needles to guide the drill, I avoid perforating the septum. If there is an exostosis, I riddle and remove it; if I can not get sufficient room by this procedure, I take away part of the turbinated tissues or bone.

Dr. Bosworth: I must compliment Dr. Asch for presenting a most ingenious intranasal splint. It corrects not only vertical displacement, but horizontal displacement as well.

In reply to the last remark of Dr. Jarvis in regard to removing the turbinated bodies, I wish to ask if it is not unjustifiable to remove an important organ of the body simply for the purpose of admitting air through the nose? The object of the treatment is to restore normal function, not to straighten a deviated septum. I deny that it is primarily for the purpose of giving more breathing space. It is not justifiable to remove this organ, the functions of which are for the time not hampered, any more than it would be justifiable to remove a kidney for functional disorder. I do not admit that the primary object is to admit more air; that idea is based upon an entirely erroneous conception of the purpose of the operation.

Dr. Jarvis: The primary object is not cosmetic; in my mind it is to remove an obstruction and afford more breathing space.

Dr. Mulhall: I wish to say a word in defense of Steele's forceps. The objection has been raised that it does not cut through the septum. It is evident from the discussion that the gentlemen have been talking about two entirely different things, a deviated septum and a thickened septum. Steele's forceps will not pass through a thickened septum, it is true. When I get such a case, I first treat the hypertrophy and reduce the thickened septum to its normal size, and then apply the forceps, and find no difficulty in making the blades meet. Then, again, the Chair has stated that there was a great tendency to recurrence of the deformity after operation. This is true, but I have never seen the recurrence complete. After the cutting I push the septum over and make it project upon the opposite side, using the handle of a tooth-brush to force it over. I then plug the affected side with a rubber nipple stuffed with cotton. There may be some return, but never to the original extent.

Dr. Ingals: As intimated by the author, the secret of successful treatment is, destruction of the resiliency of the septum during the operation, which renders the after-treatment simple, but if this is neglected the patient can not tolerate suitable plugs or splints, and imperfect results must follow. I have had patients wear tubes of gutta-percha from four to six weeks without discomfort, and I have found the results of the operation very satisfactory. Where there is great thickening of the septum with deflection the excess of tissue must be removed.

The President: I did not mean a thickened septum, but in ordinary cases of deformed septum I have used Steele's forceps and could not get it to close. I could not cut through thick paper with Steele's forceps, but with other forceps I cut through six thicknesses of chamois skin.

Dr. Daly: The object being to get rid of the resiliency of the septum, it can be accomplished with Steele's forceps. I have never experienced any difficulty, but I do not satisfy myself with a single cut; I make two or three incisions irregularly in the septum to break up the cartilage. The fact that the cutting blades of the forceps do not perforate the septum is an advantage. The operation should not be done too early in life. If we wait until the patient is old enough to appreciate the importance of the operation and co-operate with us in our after-management, we shall usually be successful.

Our success in operating depends sometimes upon very simple things. I wish to show my plan of plugging the nostril. Take some absorbent cotton and make a little roll about as large as my middle finger; around this wrap some ordinary grocer's white cotton cord from one end to the other in a long spiral. Now, if we fold this in the middle, and, after tying the ends, apply vaseline, with a styptic or antiseptic, and carry it deep into the nasal chamber, the ends with the cotton twine are external and may be cut off. When it is desired to remove the plug, it is only necessary to pull both ends of the cotton string and it comes out entire with the cotton plug in its embrace. I have found this expedient a great saver of time and trouble. I have also used it in cases of nasal hæmorrhage. It

can be dipped in iodoform or some styptic, if desired. I consider it a very good point in practice.

Dr. HOLDEN: As the discussion is upon deviated septum, it may be of interest to present a case illustrative of the difficulties one may encounter from recurrence. It is that of a young lady, an artist, of fine appearance, but who unfortunately had a seriously deviated septum. She was very much annoyed by it and was willing to submit to any operation for its correction provided there should be no perforation. The septum was thin and rather mobile, and crackled like parchment under the finger when it was moved. It was so thin that I feared a cutting operation might produce a perforation. With a periosteal elevator the cartilage was set over and retained with an antiseptic cotton compress. In three months' time the deviation had recurred. I then repeated the operation, forcibly pressing the septum over to the opposite side. The relief was all that could be desired, but in two months there was again deviation. She was resolutely determined to have the deformity corrected, and I now made two semi-lunar incisions and removed an ovoid piece of the cartilage by careful dissection, and used compresses as before. The deformity returned. The redundant portion of the (fortunately now thickened) septum was sawed off without perforation. The result was good for several months, but she returned just as bad as she was before. I then resorted to Steele's forceps, crushed the septum at two points, set it over in place, and also crushed the osseous septum at its junction with the cartilage, making in all three incisions. An ivory plug was introduced slightly hollowed out on one side for the turbinated bone. This was wrapped with a very thin film of bichloride cotton. She wore this ivory for five days before removal, and continued to wear it altogether for five weeks. The result is satisfactory save that there is some projection at the base of the cartilaginous septum, which may yet require another operation by saw or drill.

Dr. ASCH: I feel very much pleased that the paper has provoked so much discussion; it shows that I was not mistaken in my estimate of the importance of the subject. Part of the discussion, however, seems based upon a misunderstanding of my remarks, or perhaps I may not have expressed myself clearly. I said that the success of the operation depended upon overcoming the resiliency of the septum, and placing it in proper position. The resiliency being overcome, the splint is introduced, which causes no irritation; the nostril is plugged lightly; there is no trouble whatever, and in a very few days the parts are healed. With regard to Steele's forceps, it was owing to my failure to succeed with that instrument that I was led to devise these scissors. I found that it did not completely penetrate the cartilage. In the plan of operating recommended by Dr. Jarvis, the resiliency of the cartilage is not overcome, and the deformity will therefore be reproduced. With reference to his criticism upon the plug, I may say that I never experienced any difficulty arising from it, or observed any signs of septic infection.

The Early Diagnosis of Malignant Disease of the Larynx.—Dr. D. B. DELAVAN read a paper with this title. (See page 508.)

The PRESIDENT: This is an exceedingly important subject. Upon the early diagnosis the life or death of a patient may depend.

Dr. DALY: This subject is certainly an important one—not only involving questions of diagnosis of a very interesting character, but the safety and happiness of our patients. I may say at once that I am not very favorable in these cases to much interference unless of a radical surgical character. I think that there comes a time when a benign sore becomes irritated by harsh interference, and, where the conditions are predisposed, may be made malignant by such harsh interference. We want to learn more about this point and how to avoid this dread evil. I have no very pronounced views of treatment, except that I am not an advocate of extirpation of the larynx; it is a ghastly operation, the result is not happy for the patient, and statistics do not prove that it is justifiable.

Dr. INGALS: I would ask what the difference is in the appearance of the parts, in transillumination of the larynx, between a benign and a malignant growth.

Dr. DELAVAN: The only use to which transillumination can be put is to demonstrate a cloudy area around the growth corresponding with the amount of infiltration, which, of course, would not exist in benign lesions. In the normal larynx the electric light transmitted in this way gives a rosy illumination of the parts with a certain definite distribution of the lights and shadows. If one side of the larynx is invaded by a growth, and its appearance is contrasted with that of the healthy side by transillumination, the difference will be perceived. Where there is exudation or infiltration, the conducting power of the tissues is much diminished. Of course, by this method no fine diagnosis is possible, but it may be of some assistance in making a diagnosis between a simple condition of tumefaction and the actual presence of a new growth, although, of course, other means would be required to confirm it. It would determine whether the transparency of the tissues is normal, and, if not normal, the extent of the lesion. The mode of applying it is very simple. An electric lamp is attached to a cylinder of solid glass which may be as long as convenient, two inches being sufficient. The light is focused at a spot at the end of the cylinder, which is placed directly against the larynx, externally to the point to be examined. A lamp of three or four candle power will afford a brilliant illumination. Of course, the relative thickness of the wall of the neck will affect the light, in a stout person the amount of light transmitted being less than in a thin one. The light being placed directly below the cricoid, a good illumination is afforded in average cases.

Dr. INGALS: Would the transillumination of a malignant growth make it appear very different from a benign tumor? I can see that there would be a difference, for instance, between a cyst and an ordinary infiltration, but I can not understand why there could be much difference in appearance between a simple inflammatory exudation and malignant disease. I am much interested in the discussion of the early diagnosis between lupus, syphilis, and malignant disease, because of a case that I saw early this past winter. The patient, about twenty-two years of age, married, came to me breathing with much difficulty, the right ventricular band much thickened, the cord scarcely visible, owing to the swelling above it. I introduced a large-sized O'Dwyer tube, which she wore for several days; I then removed it, and breathing was perfectly easy. I afterward examined her larynx and found two or three small nodules protruding from the ventricle, having the appearance of a papillary growth. The patient afterward had *la grippe*, followed by typhoid fever. I did not see her again for two or three months, during which time tracheotomy had been performed. When she returned there were no distinct nodules at the orifice of the ventricle, but general thickening of the right side of the larynx, particularly in the region of the false cord, which might have been accounted for by a simple benign growth within the right ventricle.

The difficulties of diagnosis are well illustrated by a case that I treated some years ago, that had been under the care of the late Dr. Elsberg and another prominent laryngologist, I do not remember whom. One had pronounced it a cancer, the other not. I found extensive thickening which certainly had a malignant appearance. No possible evidence of syphilis could be found. The iodides were tried, though without much effect.

He remained in much the same condition, and I think is still living.

Dr. Holden: I should like to ask if I understood the author correctly in stating that one of the points of diagnosis was that the zone of redness surrounding the growth was characteristic of malignancy. I recall the case of a gentleman who came to me some time ago, and entirely recovered after antisyphilitic treatment. The character just mentioned—of a zone of redness—was well marked in this case. I have seen other cases in which the zone of redness existed in non-malignant growths.

Dr. Asch: My experience is that cancer of the larynx is comparatively infrequent; but I can not recall that in the cases I have seen there was, as a rule, any diagnostic peculiarity in the appearance at the outset. There is nothing to indicate malignant disease. There is first swelling in the larynx without any redness, and no change in the external appearance of the mucous membrane. Most of my cases were well developed when they presented themselves. I usually fall back upon the classical way of diagnosis by treatment. If the growths yield to syphilitic treatment, they are not cancer. If we could diagnosticate these cases early, it might be possible to save life by operation. I do not understand that Dr. Delavan gives anything which enables us to make this early diagnosis except the reddened zone of infiltration. We can exclude lupus and tubercle, because in them the appearance of the mucous membrane is changed and they are located differently. The cases of cancer I have seen have not occurred in the posterior part of the larynx, but elsewhere.

Dr. Mulhall: I wish to corroborate the point made by Dr. Daly, which is of great interest. I have had two cases of cancer of the larynx, which greatly improved under iodide of potassium for a time. I also wish to remark that we should be very careful of our prognosis in cases of suspected cancer of the larynx. I recall a case seen by an eminent laryngologist and pronounced a case of undoubted malignancy. There was paralysis of the muscles of the larynx, aphonia, the patient was losing flesh, and strength was failing. I saw the case a year later. The patient came to me completely aphonic with this same growth. The treatment proved that it was a case of chronic laryngitis, limited to one side. The treatment consisted in applications of solid nitrate of silver for the reduction of infiltration, and the galvano-cautery to the growth. Her voice returned, and she went home much relieved in body and mind Therefore I remark that we should be careful in the diagnosis of cancer of the larynx. I quite agree with Dr. Daly that the operation of extirpation of the larynx is unjustifiable.

Dr. Swain: I wish to remark upon the infiltration and the consequent immobility of the parts involved as a point in the diagnosis of malignancy. In a recent case which I recall there was a diagnosis to be made between cancer of the larynx and infiltration due to perichondritis or tuberculosis. With very little hesitation, owing to the mobility of the parts and non-involvement of the vocal cords, I decided that it was non-malignant. The subsequent course of the disease showed it to be a simple perichondritis with abscess, which was evacuated, and the patient is now better.

Dr. Bosworth: It is very interesting to listen to a paper which considers practical points, such as diagnosis or treatment. In addition to the points mentioned, there is yet another which has not been named—it is the diagnostic instinct which enables us to look at the case comprehensively and say that this is a case of cancer, or this is not malignant.

Dr. Langmaid: Some years ago I supposed that cancer of the larynx was comparatively frequent. I do not now believe it to be rare. Two diagnostic points occur to me which may be of interest. When you see the growth early you find infiltration, the lumen of the glottis is diminished, and its general aspect is changed. The other point is the occurrence of a stabbing pain in the ear; it comes early in the disease.

Dr. Daly: A further word I would say with regard to a subject of importance to laryngologists. It is a word of injunction as to the use of irritating local applications while the case is still being studied. I have in mind a very glaring case of malpractice where the patient was burned with the galvano-cautery every day for seven or nine days, sufficient of itself to develop cancer of the larynx, where the germs were already budding. If our case is one of cancer of the larynx, irritating measures short of total destruction or extirpation of the affected tissues do no good; if it is not cancer of the larynx, we have only to await developments. But if interference is practiced, let it be by early ablation or extirpation of the suspected tissue, and only by the knife and not the cautery.

Dr. Ingals: With regard to the treatment of cancer in the throat, I have been fully convinced that the application of carbolic acid, tannin, and glycerin has given much relief to patients for whom at best we can do but little. I think that, applied in this way, tannic acid hardens the tissues, and thus prolongs the anæsthetic action of the carbolic acid. I use for this purpose a combination of morphine four grains, tannin and carbolic acid each thirty grains, in four drachms each of glycerin and water.

The President: During this discussion the question of the rarity of cancer of the larynx has come up. As far as my own experience goes, I have seen very few cases in this city (Baltimore), but abroad, especially in London, it seems to me that the disease is more common. With regard to extirpation of the larynx, I do not think it an unjustifiable operation, because many lives have been saved and prolonged by it. The startling results in the experience of Hahn make us believe that we may have to look upon this operation as one to be more frequently used than it is to-day. There is one form of hypertrophic laryngitis where the membrane becomes very much thickened. Such a case might possibly be mistaken for incipient carcinoma. The fibroid degeneration of the larynx in tertiary syphilis might also be mistaken for the early stage of carcinoma, especially as on this affection the iodides do not have the slightest effect. These cases drift on to the performance of tracheotomy as the only hope of relief. In such a case, if ulceration takes place, the lesion might very readily be taken for cancer, and this mistake has very probably been made. One feature which increases the liability to mistake is the early swelling of the lymphatics of the neck. We all know that the main rendezvous for the lymphatics coming from the larynx is at the cornua of the hyoid bone. Strange to say, even in some of the worst cases of tuberculosis of the larynx, and of syphilis of the larynx, these glands have not been found affected. When enlarged, they can readily be felt by deep pressure in this locality. They become enlarged in cancer of the larynx at a very early day more frequently than is generally taught. Although this is not diagnostic, yet if I found in a suspicious case, at the cornua of the hyoid bone, a mass of enlarged indurated glands, I should consider it probably malignant. An old gentleman was brought to me the other day for me to decide upon the propriety of extirpation of the larynx. The diagnosis was very difficult, and lay between cancer and tuberculosis. Something in the appearance of the growth suggested the idea of malignancy. His physician reported to me that he had also a cavity in the apex of the right lung. He had a number of glands enlarged in the superior cervical triangle, exceedingly hard and flattened. Tracheotomy had been performed, but the tube had been removed, as the obstruction had become less since the operation.

On the strength of the appearance of the larynx and the nodules on the outside, I made a diagnosis of cancer of the larynx with bronchial dilatation on the left side, asking for two weeks' time in which to change it if I thought fit after further observation. I also warned against the danger of sudden œdema, and advised a second tracheotomy. I am now awaiting developments.* The case is hopeless in any event, and the proposed operation is ont of the question. We do not know how far the infiltration may extend, and even extirpation of the larynx might fail to remove it all. Any growth proceeding from the ventricle upon either side is a snspicious one, for this is the most frequent mode of invasion of the larynx by malignant disease. I think that Dr. Daly is a little too severe upon the use of the galvano-cautery. It certainly destroys tissne.

Dr. Daly: Not necessarily; it depends altogether npon how it is used. It will at a white heat destroy tissue, but at a dull cherry-red heat it only stimnlates and is not canstic; its action is only superficial. The parts become the seat superficially of an acute inflammation which is rapidly followed by absorption.

The President: I am thoroughly in accord with Dr. Daly about the harsh treatment of any disease, whether seated in the larynx or not. One point of historical interest I might refer to; Voltolini is supposed to have been the first to suggest transillnmination of the nasal cavities and the antrum of Highmore. I wonld call your attention to the fact that the second year that I was a member of this society I proposed this method. Two years before, the S. S. White Dental Mannfacturing Company, of Philadelphia, had submitted to me, for examination, an instrument for transillnminating the larynx with an electric lamp. This instrument had been before the public for some years, and was in use by American dentists to detect caries of teeth by transillumination. I am not positive whether or not this had been used for the antrnm of Highmore, but it certainly had been used for examining the mouth and teeth. The snggestion was made that it might be useful for transillumination of the larynx. I did not think that it possessed much valne for the larynx, but thought that it would be valnable in examining the nose. It was a small Edison light which gave the illumination. As a result of my observations, I proposed this method in the diagnosis of antral disease and deep-seated lesions in the nasal passages. I might also say, in justice to another member of this society, that at the same meeting Dr. Carl Seiler, of Philadelphia, said that he had tried this method of illuminating the larynx, but that he had given it np, I believe, because it burned the patient's throat.

Dr. Seiler: My objection was that there was no shadow, as in the ordinary method of illnmination, and the distinction between projecting parts and the rest of the larynx was lost. The whole inner surface glowed with a dull-red light, which was not sufficient for careful examination.

The President: I simply mentioned these facts to show that Voltolini was not the first to pursue this method of examining the larynx and nasal passages.

Dr. Delavan: The object in bringing this communication before yon was simply because, of all the practical observations resulting from the searching investigations lately made in this department, these alone seemed to be of any value. Thickening and infiltration are certainly of diagnostic value. The reddened zone, a point to which attention has been called hy several German writers, and which I also have observed in several cases, is not without a certain amount of significance. My intention, however, was simply to bring it forward for discussion and consideration.

With regard to extirpation of the larynx, its success depends very largely upon the selection of the case and npon the operator. Some few men can perform it and do it well, whereas with others failure seems to have resulted from lack of experience in the operation itself, or from lack of care in the after-management of the patient. In the case I have referred to the patient lived for several years and was comfortable. Several years ago, before the statistics of recent operations had been published, Dr. C. H. Knight, of this association, read a paper in which he stated that the propriety of the operation must be decided by the statistics. Since then statistics have accumnlated, and we are in a better position to judge as to the actual value of the operation.

The points of diagnosis which I referred to were not positive bnt suggestive. There is, as has been said, a training of the observation by which we may be enabled to strongly suspect malignancy without being able to say upon what the opinion is based—something abont the locality and appearance which stamps its character npon it.

With regard to the astringent applications mentioned by Dr. Ingals, I have found them of decided valne; they afford great relief to pain in swallowing, and I think that they sometimes delay the development of the growth. They can not have mnch effect npon the deeper portions, but they appear to harden the surface and protect it. I have seen a great many cases of cancer of the larynx in the last fifteen years in private and hospital practice, and believe that in our city (New York) it is not snch a very rare disease. The swelling of the glands of the front of the neck which has been mentioned may be found in other lesions. It may be absent in cancer, especially early in the case. Finally, if the paper has succeeded in demonstrating the poverty of our resources in the early diagnosis of laryngeal cancer, and if it will serve to stimulate investigation in this direction, it will have heen of some use. Certainly, little substantial has been learned from the much-discnssed case of the late Emperor of Germany.

* Since this was spoken the patient has died, death occurring suddenly from laryngeal œdema, the operation not having been performed. Microscopical examinations showed the laryngeal and cervical growth to be cancerous. On dissection, there was extra-tracheal cancer, with considerable pressure on the windpipe. There was also left bronchia dilatation.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNÆCOLOGY.

Meeting of November 28, 1890.

Dr. R. A. Murray in the Chair.

Exploratory Puncture of the Female Pelvic Organs.—Dr. G. M. Edebohls read a brief summary of his points for the benefit of those who were not present at the reading of the original paper at the previous meeting.

Dr. A. F. Currier said he thought with the anthor of the paper that the only cases in which the pnncture was admissible were those in which a diagnosis conld be made in no other way, and even then the qnestion of danger would have to be taken into consideration. The danger might not exist in the hands of the experienced, but the procedure was liable to be adopted by those who were incompetent, and then disastrous resnlts would be sure to follow. One of the first dangers was that of punctnring the intestines, an accident that could scarcely he avoided in these cases, as adhesions binding down the intestines were so often found in laparotomies. It was a grave qnestion when one considered that, in pnnctnring, the needle was liable to pass through the intestines, allowing some of the contents to escape into the peritoneal cavity, and in cases of pyosalpinx for pns to find its way along the line of puncture to the same dangerous

situation. The speaker thought that if this method was called for at all, it would certainly be limited to a very small number of cases. He felt that with careful antisepsis and the use of anæsthetics the pelvic cavity could be fully explored and a diagnosis made without subjecting the patients to the dangers of puncture.

Dr. A. H. Buckmaster was not in favor of the operation. He gave the history of a case of ovarian cyst where, after puncture of the sac, suppuration had taken place, general peritonitis following, and death. The puncture had been made with the greatest care, a small-sized needle being used. The speaker was surprised at the good results reported by Dr. Edebohls in using this method. He thought that in searching for pus in the pelvic cavity he would much prefer to make an incision, as in using the puncturing needle in one case for this purpose he had opened the bladder.

Dr. Jewett's views were in accord with those of the last two speakers. He thought that if puncture could be made directly into the sac the operation might be available, but that if the needle had to pass through the intestines and twice through the peritonæum it was decidedly dangerous.

Dr. A. P. Dudley said that he rarely opened an abdomen without finding the intestines were in front or adherent in the pelvis, and in position to be punctured if that operation were performed, and he thought passing a needle through the intestines was always dangerous, let alone passing it twice through the peritonæum. It was his practice, in cases in which the operation was called for, to puncture through the vagina. The history of a case was related where an enlargement presented behind the uterus. A satisfactory history could not be obtained, but, as far as could be learned, there was nothing to indicate tumor, hæmatocele, or inflammation. He had punctured *per vaginam* and drawn off twelve ounces of blood. To-day he had made another puncture with a needle an eighth of an inch in caliber, but had been unable to discover anything. After an incision he had drawn off three ounces of pus. He concluded that the case had originally been one of hæmatosalpinx resulting in pyosalpinx, and that if he had been satisfied with an exploratory puncture the bad results would have been obvious.

Dr. H. J. Boldt said that, as a rule, he was opposed to puncture of any kind, for the reason that it was possible to tell in almost every case whether the trouble was intraperitoneal or extraperitoneal without doing this. For a positive diagnosis to be made the needle would have to be larger than would be proper to use, because the pus would not pass through the fine ones. An incision was preferable in cases where pus and cheesy masses were supposed to be present. He thought that with the patient under an anæsthetic a good diagnosis could be made, and for this purpose he did not like the puncture at all. He had been surprised to hear Dr. Edebohls say that it did no harm to puncture the intestines.

Dr. H. O. Coe thought that in puncturing through the abdominal wall there was always danger of injuring the intestines and blood-vessels, and that this could almost always be avoided by operating through the vagina; but even this was not without its drawbacks. He preferred the exploratory incision to puncture. He could not think that Dr. Edebohls's method would be generally accepted.

The Chairman said that it was always a temptation to puncture to find out what the tumor was in such a case, but in his hands the method had not been successful. Of course Dr. Edebohls had used every precaution in his cases, but the result of puncture of the intestines was well known. He thought that puncture ought never to be done by persons who were not competent to do laparotomy if it was necessary, and that under any precaution the operation was fraught with grave dangers.

Dr. Edebohls had expected objection to his method, but he thought that the points in his paper had been overlooked by most of the speakers, as his method did not refer to large tumors, but to small masses which lay deep in the abdominal cavity. He did not mind the intestines being punctured. He had, after operating, kept the patients under observation from a day to fourteen days, and had never had any bad results. He did not recommend the method to the general practitioner, but only to the expert, and it was only to be employed in those cases in which a diagnosis could be made in no other way. The method had never been used for its therapeutic value, although some patients had been cured by the removal of the contents of the sac. He only used an anæsthetic in puncturing when he could not do without it. About three quarters of his patients had been operated on without an anæsthetic. He insisted again that his method was not for the general practitioner, but for the expert, and that, if perfect asepsis was practiced, the needle introduced steadily, and the inclination to move the needle about resisted, the results could not fail to be good.

Dr. Dudley asked whether an operation had ever been done on one of the patients that had been previously punctured, and if so, whether any adhesions or thickening had been found along the line of puncture?

Dr. Edebohls said that he had had no opportunity to make such an examination, but that it was well known that, even in gunshot wounds of the intestines, them ucosa filled up the gap very rapidly, and that he did not think that the small needle which he used would allow any fæcal matter to flow out and cause general peritonitis.

The Manikin in the Teaching of Practical Obstetrics.—Dr. J. C. Edgar read a paper with this title. (To be published.)

Dr. Jewett said that this subject was one of great interest and one that had not received the attention which it ought. It was almost impossible to get sufficient material for students, and the well-made manikins and appliances that could now be procured were of great value in teaching obstetrics. It was his opinion that this was the only way in which the student could be trained in this branch.

Dr. H. T. Collyer related the history of a case of forceps delivery which he had been called to see, after it had been worked at by several other physicians, in which the mutilation of the patient was simply fearful. It was the opinion of the speaker that if his colleagues had had manikin training such things could not have happened.

The Chairman had had twelve years' experience in the use of the manikin as a means of teaching practical obstetrics and he was convinced that it was the only means by which it could be properly impressed. In the first place, even if one had a patient for the purpose, it was impossible to let a whole class examine her, and if they did they could not see into the uterus and appreciate what was going on. It was the same thing in the application of the forceps on the human subject. The student had to take the word of the instructor as to what position it was in in the uterus, and it was a pretty hard thing to understand without seeing. In the use of the manikin a fœtal cadaver could be used, and the forceps be applied and the student see what he was doing. In this same way all the capital procedures might be performed. He strongly advised this method of teaching obstetrics, as only one out of every twelve physicians could get the opportunity of having maternity training. He thought that the gynæcologists' material was supplied by the obstetricians, and that this was due to a lack of knowledge of even the first principles of midwifery. One of the most important things that a student should know was pelvimetry. With this fact in mind, an examination should always be made before labor came on. In spite of the large number of obstetrical

operations done, the mortality was kept down pretty low; but in all teaching of obstetrics the student must be told to use the forceps only when it was necessary.

Dr. Coe had had considerable experience in the use of the manikin and cadaver in teaching operative gynæcology, but thought that the well-appointed manikins were to be preferred, for the reason that work on the cadaver was not compatible with that of the practitioner, obstetrician, or gynæcologist.

Transperitoneal Hysterorrhaphy; a New Method of Ventro-fixation of the Uterus without opening the Abdominal Cavity.—This was the title of a paper by Dr. Florian Krug. (To be published.)

Dr. H. J. Boldt thought that one of the disadvantages of the operation was the introduction of a sound into the uterus, and the force necessary to hold the uterus against the abdominal wall, which was, the speaker thought, in some cases a dangerous proceeding, as some uteri were so soft that the sound would penetrate them. Taken altogether, he could not see the advantage of the operation; for his part, he should prefer to make the regular incision. As for ventral fixation, no matter what operation was done, he was not prepared to comment on its merits, as the permanent results were not known, and certainly, from theory alone, he could not say he thought it successful.

Dr. Dudley thought that Dr. Krug's operation was ingenious; that if the uterus would remain adherent, and if the results were good, he should be glad to indorse it. But he thought adhesion of the uterus to the abdominal wall quite as much of a pathological condition as the retro-displacement, and that, with the uterus firmly fixed in this position, it would be subjected to a great deal of pressure, both from above and from below. There was no doubt that if an operation could be performed years after such fixation, the adhesions would be found stretched and dragged. He thought any operation which would straighten up the uterus without fastening it to the abdominal wall would be preferable; still, if he had a case of movable uterus that had resisted other means of treatment, he should be inclined to try this method.

Dr. Currier thought that the objections to the operation were very considerable. In the first place, he saw no need of exposing the woman to dangers the result of which one could not be sure of. Then, again, he thought that puncturing the uterus was not without danger, and that scraping or denuding it, when it could not be observed to what extent this was done, was also unsafe. He should be glad to know of something that would cure those cases of retro-displaced uteri of non-inflammatory origin. For his part, he did not feel like doing an abdominal section in such cases. About the merits of the new operation he was not prepared to speak, but Dr. Polk had said that in uteri which had been previously so attached he had found the adhesions loosened after a time.

Dr. Edebohls said that the success of such operations depended upon the firmness of the peritoneal adhesions, but if this could be avoided, so much the better. In his own practice he did a modification of Alexander's operation. Twenty-one patients in all had been operated upon, and the results had been very satisfactory.

Dr. Jewett's experience in this operation had been limited to one case only, but, from what he had seen and heard, he did not think the operation devoid of danger.

Dr. Dudley would like to know how it could be told whether the uterus was adherent or not. He had performed laparotomy in three cases after operation for the purpose of fastening the uterus to the abdominal wall, and had never been able to find any adhesions.

The Chairman thought that considerable good might be done to the uterus by having it held in position for a while, even if the adhesions did loosen after a time; at any rate, he thought it a good thing to try.

Book Notices.

A Manual of Modern Surgery: an Exposition of the Accepted Doctrines and Approved Operative Procedures of the Present Time. For the Use of Students and Practitioners. By John B. Roberts, A. M., M. D., Professor of Surgery in the Woman's Medical College of Pennsylvania, etc. With Five Hundred and One Illustrations. Philadelphia: Lea Brothers & Co., 1890. Pp. xvi–33 to 800. [Price, $4.50.]

This book is a most excellent one for speedy and satisfactory reference. It is essentially a work expressive of its genial and learned author's well-digested thought and experience, and may therefore be received as a guide in practice fully up to the period, and philosophically conservative. For medical students, especially the overworked American, and those who have neither the inclination nor the leisure to prune and plod for themselves, the book is invaluable. The initial chapter, on inflammation and kindred subjects, is a clear and concise *résumé* of modern views, and could not well be more happily worded or adapted to easy understanding. The chapters on injuries of the brain and spinal cord and their treatment are particularly worthy of commendation and evince the nicest discretion in their preparation and much original labor. The book abounds in useful, well-selected, and well-drawn illustrations. It is not only worth its selling price, it is worth owning and reading.

The New York Academy of Medicine.—At the next meeting of the Section in Laryngology and Rhinology, on Tuesday evening, the 23d inst., Dr. J. W. Gleitsmann will read a paper entitled Experience with Trichloracetic Acid in Two Hundred Cases of Affections of the Throat and Nose, with Demonstrations of Instruments.

At the next meeting of the Section in Obstetrics and Gynæcology, on Friday evening, the 26th inst., Dr. Malcolm McLean will read a paper on The Placenta, Funis, and Membranes—some Remarks on their Influence in Gestation and Parturition, and Dr. R. A. Murray will open a discussion on The Diagnosis and Management of Concealed Hæmorrhage during Labor.

Tomato Poisoning.—"Under this title Dr. Mills (*International Dental Journal*) describes a form of recession of the gums of the superior molars, which he believes to be due to the use of tomatoes as food. The affection is most marked on the palatine surfaces. Great sensitiveness is manifested along the line of recession, similar to that of an exposed nerve. The only remedy was found to be abstinence from tomatoes. If the disease continues, the teeth fall out, not usually more than one being lost in a season."—*Druggist's Circular and Chemical Gazette.*

ANSWERS TO CORRESPONDENTS.

No. 338.—Half an hour.

No. 339.—There is no essential difference.

No. 340.—It is not known. The active constituent is conjectured to be a ptomaine.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

THE MANIKIN IN THE TEACHING OF PRACTICAL OBSTETRICS.*

BY J. CLIFTON EDGAR, A. M., M. D.,
ADJUNCT PROFESSOR OF ORSTETRICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK;
ATTENDING PHYSICIAN TO THE OUTDOOR POOR DEPARTMENT OF BELLEVUE HOSPITAL, DISEASES OF WOMEN;
ATTENDING PHYSICIAN TO THE MIDWIFERY DISPENSARY.

THIS subject will be discussed under three headings:

I. The necessity for practice upon the manikin or cadaver before actual attendance upon labor cases.

II. A description of the various manikins and their accessories now in use.

III. What may be accomplished with the improved obstetric manikins.

I. *The Necessity for Practice upon the Manikin or Cadaver before Actual Attendance upon Labor Cases.*—What relation do demonstration, practice, and operation upon the manikin bear to clinical instruction in midwifery?

It is the belief of the writer that practice upon suitable manikins should precede actual attendance upon labor cases and the performance of obstetric operations. We are told † that in a collection of 100,000 labors occurring in the maternity hospitals of St. Petersburg, Berlin, Dresden, Leipsic, Marburg, Munich, Würzburg, Prague, Vienna, Graz, and Laibach, 6,555 operations were demanded—in other words, one operation in every 15·2 labors. The relative frequency of these operations is variously distributed over the performance of such operations as the application of the forceps, internal version, detachment of the placenta, extraction in breech cases, reposition of the prolapsed funis, induction of premature labor, perforation, cephalotripsy, Cæsarean section, reposition of prolapsed extremities, etc. The operations just cited are named in the order of the frequency in which they were demanded.

In 606 cases of labor occurring in the Nursery and Child's Hospital during the time my friend, Dr. Irwin H. Hance, was house physician in that institution, operative interference was demanded in 59 cases, or 1 operation in every 10·2 labors. These figures take no account of 17 cases of pelvic presentations, where undoubtedly some interference was resorted to for the extraction of the after-coming head or arms. These operations included—

Forceps (low operation)	42
" (high operation)	7
Correction of face presentations	3
Version	3
Craniotomy	1
Induction of premature labor	3
Total	59

Dr. Hance further informs me that in a recent twelve weeks' service at the Maternity Hospital on Blackwell's Island the total number of deliveries was 106. In this number operative interference was resorted to 25 times, or 1 operation in every 4·2 cases. These operations included—

Forceps (low operation)	19
" (high operation)	2
Version	4
Total	25

In the service of the Midwifery Dispensary of this city—a lying-in service carried on in the tenement-house districts of the east side for purposes of clinical instruction, in which the patients are delivered at their own homes, and in which the practice of the attending physicians has been a conservative one—during the first ten months of its existence, recently completed, there were 160 cases of confinement attended, or 131 cases at full term, if all cases of premature labor, abortion, and those seen during the puerperium are omitted. In the 131 cases of labor where delivery occurred at full term, operative interference was demanded in 8 instances, or 1 operation in every 16·3 cases of labor. These operations included—

Forceps (high operation)	1
" (low operation)	1
Podalic version	2
Manual extraction in pelvic presentations	4
Total	8

Since, in estimating the frequency of operative interference in the 606 cases of labor occurring at the Nursery and Child's Hospital, in the 106 at the Maternity upon Blackwell's Island, and in the 131 in the service of the Midwifery Dispensary, no account is taken of the operation for the manual extraction of the placenta from the uterine cavity, it is quite evident that, should this operation be added to the above named, the frequency of operation would consequently be somewhat greater than the foregoing figures—1 in 10·2 cases, 1 in 4·2 cases, and 1 in 16·2 cases, respectively—would indicate.

"In private practice Ploss found that in almost every country the frequency of operation gradually increases.* He ascribed this increase to the greater number of male obstetricians, and stated further that 'more operations were performed in cities than in the country, and that the frequency of operation bore a direct relation to the relative number of obstetricians.'"

If the foregoing statement—namely, that operative interference is demanded in maternity hospitals once in every 15·2 labors—is true (and this, from the figures quoted, is not by any means a high estimate), the question naturally comes home to each one of us: How may the student, how may the practitioner who has had no maternity service, obtain the requisite amount of practice and skill for the performance of obstetric operations in private practice? Is one justified in simply waiting for such cases to arise in his practice that may demand operative interference in order to obtain the necessary dexterity?

* Read before the Section in Obstetrics and Gynæcology of the New York Academy of Medicine, November 28, 1890.

† Ploss, quoted by Winckel, *Text-book of Midwifery*, Philadelphia, 1889, p. 602.

* Winckel's *Text-book of Midwifery*, Philadelphia, 1889.

It goes without saying that the student, for instance, is scarcely liable to obtain an insight into operative obstetrics by attending the two, four, six, or eight cases of midwifery that are prescribed by his college course. The surgeon who has a certain operation before him has already made himself familiar with the *technique* of the same by reason of his labors in the dissecting-room and repeated practice upon the cadaver. Instruction in operative surgery upon the cadaver is common enough. It is the exception for a medical college to be without it.

Has every medical college its course in operative obstetrics?

In Germany the performance of obstetric operations upon the manikin goes hand in hand with the student's observation and practice in the delivery and puerperal wards. The surgeon, and to a certain extent the gynæcologist, obtain their preliminary training by operating upon the cadaver. Can not the obstetrician do the same? Most assuredly he can. Practically, however, this is only possible in large maternity hospitals, where the service is enormous and where deaths are constantly occurring among the recently confined, a state of affairs not often met with in the present state of obstetric medicine and surgery.

Because so difficult to obtain in a proper state and because repeated operation soon renders the resistance offered by the soft parts practically useless for demonstration, and since the supply of subjects is so exceedingly small, we find the cadaver of the puerperal woman but seldom resorted to for purposes of obstetric demonstration and operation.

Upon some other means, therefore, are we forced to fall back, and necessity, the mother of invention, has called into existence the obstetric manikin. Brought first into prominence, in all probability, some time in the latter part of the seventeenth century, the obstetric manikin has passed through many changes, and numerous improvements have been made in its construction, until to-day we have at our command manikins which, according to many of the best German, French, English, and American authorities upon the subject, are in no way inferior, for purposes of diagnosis, demonstration, and operation, to the cadaver of a puerperal woman, in the recent state, whose pelvis is still covered by the soft parts.

Indeed, some go further and maintain that the later improved obstetric manikins that permit of the production of normal and deformed pelves at will, together with a number of still-born, full-termed children, are even more desirable than the cadaver and answer every requirement.

II. *A Description of the Various Manikins and their Accessories now in Use.*—Two obstetric manikins are to-day well known and in general use.

These are the French manikin, known as the Budin-Pinard,* and the German one, known as the manikin of B. S. Schultze,† of Jena.

Fig. 1 shows the Budin-Pinard manikin closed, and in Fig. 2 a longitudinal mesial section of the same is shown, bringing into view the internal arrangement.

* Manufactured by Raoul Mathieu, Paris. Price, 500 francs.

† Manufactured by Ed. Schilling, Jena, Germany. Price, 120 Marks.

The Budin-Pinard manikin is carved from one solid piece of wood, and represents that portion of the female body extending from a point just above the mammary

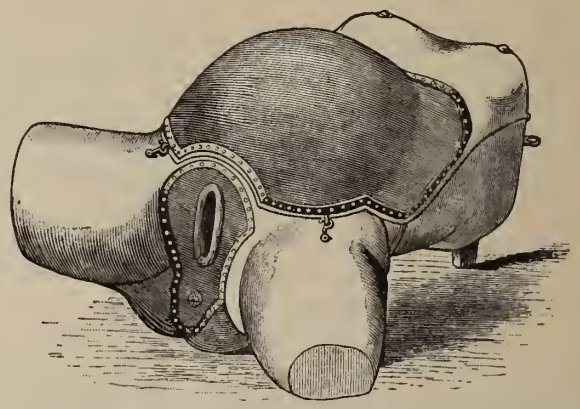

Fig. 1.—The Budin-Pinard manikin. External surface, presenting rubber vulva, anus, and inflated anterior abdominal wall.

glands to within a few inches of the knee joints. The thighs are widely separated for convenience in operating, and the anterior abdominal wall is made of rubber capable of being distended with air, and so arranged upon a

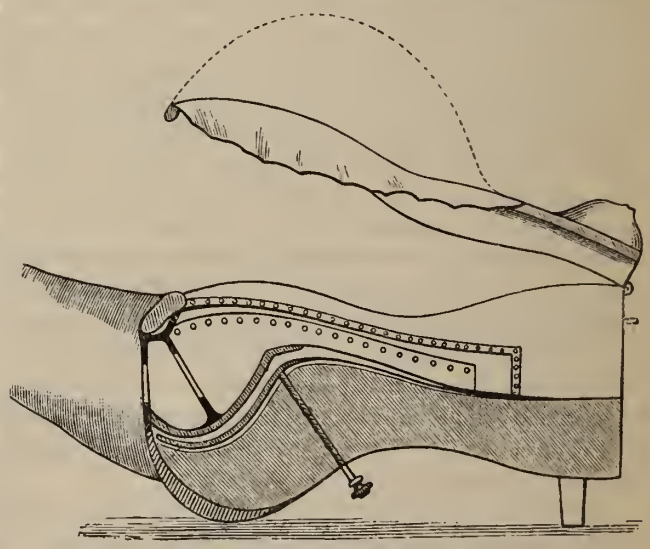

Fig. 2.—Budin-Pinard manikin seen in section.

frame hinged to the upper part of the body (Fig. 2) that the whole may be thrown back, thus bringing the abdominal cavity and pelvic inlet into view. The pelvic excavation is so carved as to roughly represent the normal bony pelvis, and one piece of India rubber lines the abdominal and pelvic cavities, and at the pelvic outlet is so molded and secured to the margin of the inferior strait as to form the vulva, ostium vaginæ, and perinæum.

The rubber soft parts are replaceable by means of metal plates and screws when worn out, and this must be attended to not infrequently if the manikin is in constant use. A false sacrum is so arranged, by means of a rod running in a groove at the posterior part of the abdominal cavity, together with a thumb-screw at its extremity, that any required diminution of the antero-posterior diameter at the inlet may be produced.

A recent improvement has been added to this manikin

in the shape of a rubber rectum, by means of which recto-vaginal and recto-abdominal palpation may be practiced, as well as various obstetric operations that require rectal manipulation, for example, Ritgen's method of manual extraction of the head, when lying low in the pelvic cavity (Fig. 3). Various methods of perineal protection may likewise be practiced by means of this improvement. Another improvement, not so recent in character, is that of a rubber uterus shown in Fig. 4.

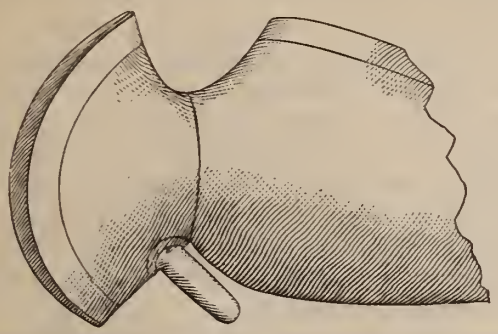

Fig. 3.—The rubber vulva, vagina, and rectum, and part of the uterus used in the Budin-Pinard Manikin.

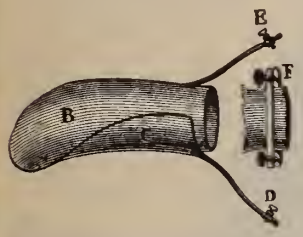

Fig. 4.—The rubber uterus (French model). B, cavity to contain fœtus and water; C, cavity distended with air; D, tube opening into C; E, tube opening into B; F, metal clamp to close B.

It consists of an India-rubber pocket containing two compartments, one of which is closed by a metal clamp at F, and is intended to contain a fœtal cadaver together with a quantity of water, which latter is to represent the liquor amnii. The other compartment, which partially surrounds the first, is to be distended with air by means of a Davidson syringe, in order to imitate the resistance of the intestines partially distended with gas.

The above-mentioned rubber uterus with its inclosed fœtus and fluid, and partially surrounded by air, is valuable for abdominal, vaginal, and combined palpation, for diagnosticating the presentation, position, and attitude of the fœtus by these means, and for practicing and appreciating that sign of pregnancy known as ballottement.

The objections made against the Budin-Pinard manikin are numerous. So much rubber enters into its construction, both in the anterior abdominal walls and the lining to the abdominal and pelvic cavities, and in the formation of the vulva, and the material is of such light quality, that repairs are constantly demanded if the manikin is used at all continuously.

The writer's experience at the University Medical College, where two of these French manikins are in constant use, has been that one college session is quite sufficient to pretty thoroughly use up the rubber representing the soft parts, and to necessitate its entire renewal. These parts are as yet not to be obtained in this country, and considerable delay and inconvenience at times attend the importing of them. Moreover, the manikin can be used in but one position—the dorsal one. Because there is no motion at the hip joints, nor attempt to imitate nature in the construction of the back of the figure, neither abdominal nor thoracic bandages can be properly applied. The pelvis itself is so roughly constructed that only an approach to the normal condition is obtained.

This manikin, however, has many advantages. It is comparatively light and readily moved from one table to another. It is compact, and, when kept in constant repair, one of the best manikins we have at our disposal. It is alleged for it that it is the best manikin known to the profession for the purpose of practicing abdominal palpation. This, however, is better and more easily taught and learned upon the pregnant woman, and rarely is there any difficulty in securing suitable cases from the dispensaries for this purpose.

In Germany to-day the most popular obstetric manikin in use in the various universities is that designed by Professor B. S. Schultze, of Jena.

It is the belief of the writer that the Schultze manikin possesses more advantages and fewer disadvantages than the Budin-Pinard figure.

As may be seen from the cuts, the figure consists practically of a square box so arranged upon segments of circles as to be capable of being rotated in either lateral direction 90°. Set into this box, which is made of hard wood, is a true bony pelvis, covered throughout its whole extent with strong, heavy leather. The angle which the plane of the pelvic inlet makes with the horizon is the same as that made when the woman reclines in the ordinary dorsal posture. An apron of chamois skin represents the anterior abdominal wall, and is so adjusted as to inclose the pelvic cavity and enough additional room to give space for two fœtuses if need be.

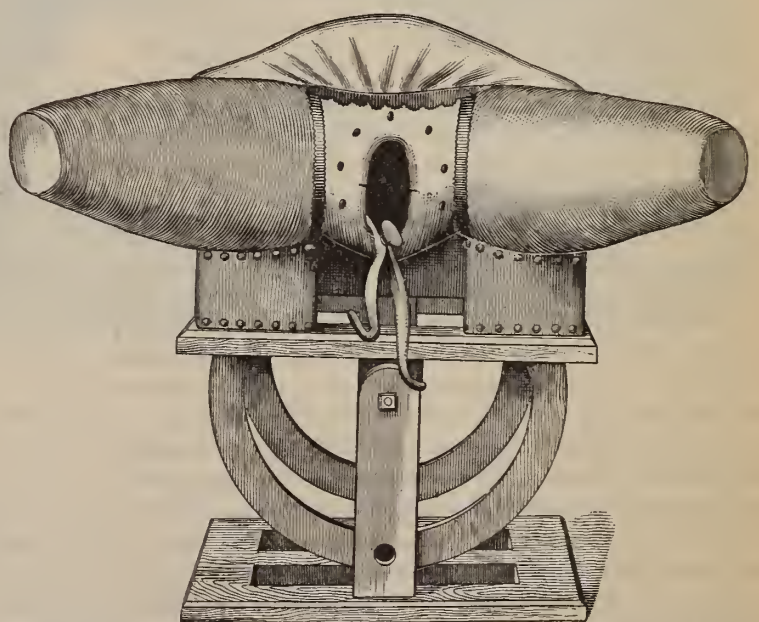

Fig. 5.—B. S. Schultze's manikin seen from the front. The forceps applied to the head lying in the first obliqne diameter.

The pelvic outlet is partially closed by one solid piece of India rubber, which represents the vulva and pelvic floor. In order to imitate pelvic deformity, zinc castings of various shapes and sizes are brought into use, which by a simple contrivance may be fastened to the sacral promontory, or removed from the same in a very short space of time. The thighs, widely separated, are covered with thick, smooth leather, and the whole figure may be securely fastened to a table or a pair of chairs by means of strong clamps.

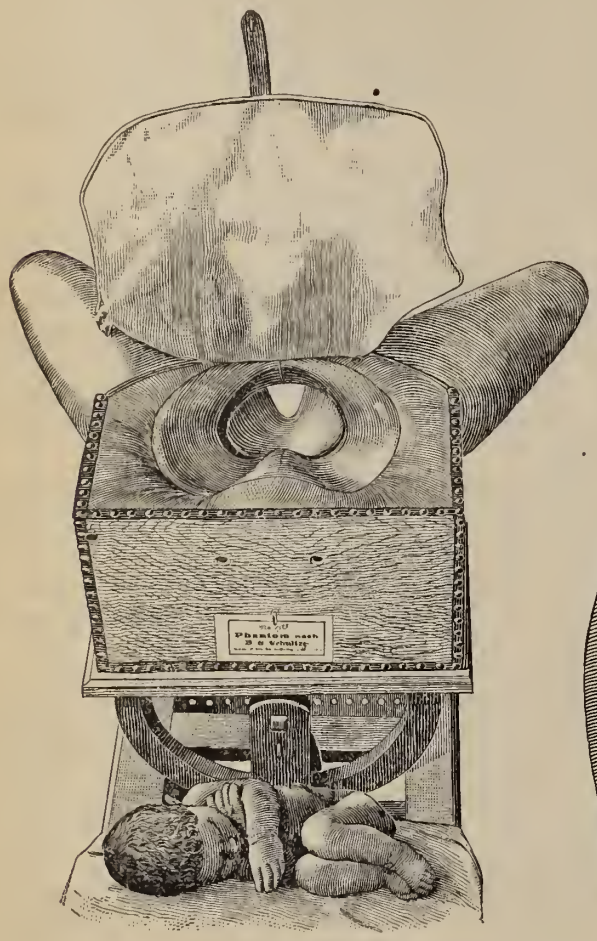

Fig 6.—B. S. Schultze's manikin, as seen from above, looking down into the pelvic inlet.

Such an obstetric manikin as this possesses many advantages and very few disadvantages. It contains a true bony pelvis in its construction, which gives us much greater accuracy than in the case of the Budin-Pinard figure. It is durable. It rarely requires repair. With the exception of the pelvic floor, no rubber enters into its construction, all the remaining parts being made of hard wood, leather, or bone.

One of these Schultze manikins, of the later improved pattern, the writer has had in almost daily use in various classes at the University Medical College for over two years, and it still shows no bad results of the severe usage to which it has been subjected; while, in the case of two Budin-Pinard manikins, used for the same length of time, repeated repairs have been called for.

A useful accessory, which may be used with either the Schultze manikin or that of the writer, is a rubber uterus,* invented and first used by Professor F. Winckel, of Munich (Fig. 7).

Fig. 8 represents an outline cut of the same.

It makes with either manikin an exceedingly useful combination, as it possesses a dilatable cervix and vagina, and many obstetric manœuvres, not otherwise easily demonstrated, may be shown—*e. g.*, the introduction of Barnes's rubber dilators and manual dilatation of the cervix.

Another advantage of the German manikin is that the pelvis may be readily and quickly placed in the lateral posture during any step of an operation, which is practically impossible with the French figure.

Here again, however, as in the French manikin, the hip joints are fixed. The thighs must remain in the same position for each and every operation.

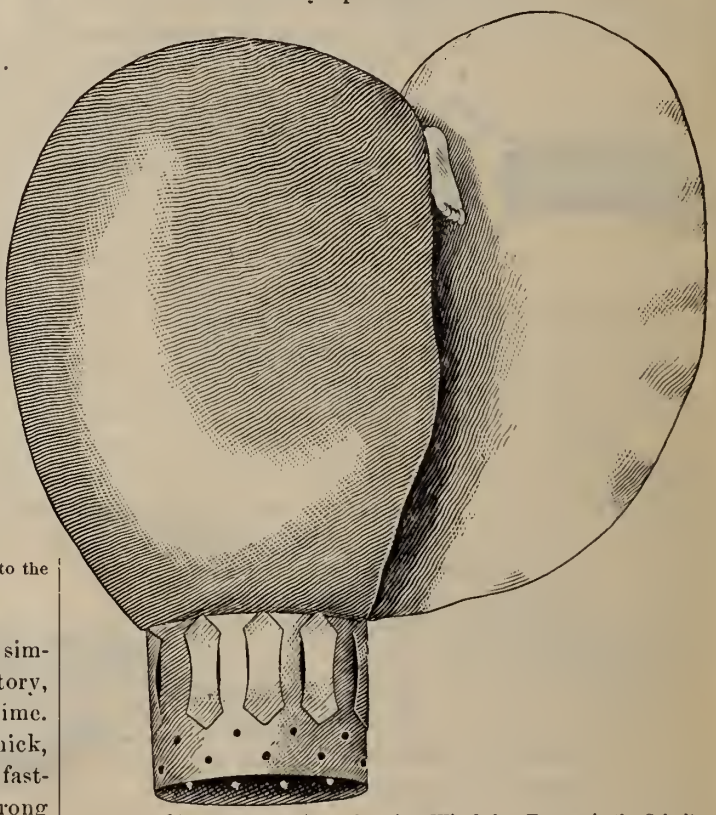

Fig. 7.—Rubber uterus, cervix, and vagina (Winckel). For use in the Schultze manikin, or that of Professor Parvin and the writer.

The pelvis being placed in a square case, no opportunity is offered for the application of bandages, either abdominal or thoracic, or for measuring the various external pelvic diameters with the pelvimeter.

Another valuable accessory to the Schultze manikin, and one which may now be obtained from the manufacturer,† consists of segments of the lower uterine segment, including the cervix. These segments come in sets of five, are made of good rubber, and are so arranged as to fit accurately into the pelvic cavity of the Schultze manikin or that of the writer. Each segment represents the os in a different stage of dilatation, so that, by simply changing

* Manufactured by Metzler & Co., 8 Kaufinger Strasse, Munich, Bavaria.

† Ed. Schilling, Jena, Germany.

them in the manikin, the entire course of the first stage of labor may be demonstrated to the person palpating, as well as the effect of such dilatation upon the presenting part of

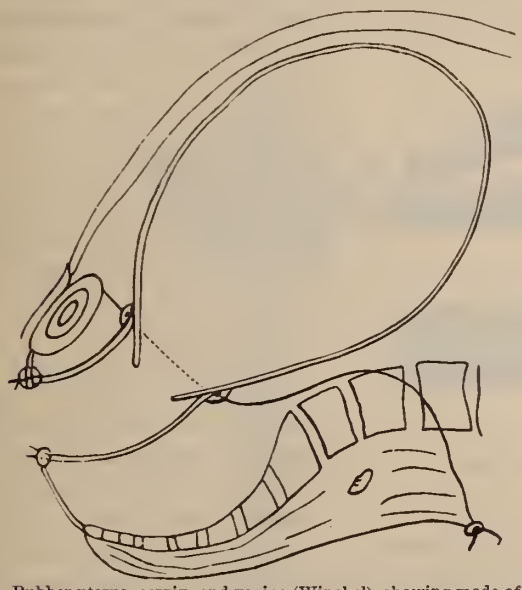

FIG. 8.—Rubber uterus, cervix, and vagina (Winckel), showing mode of attachment by means of cords to the pubes, vulva, and lumbar region of the Schultze manikin.

the fœtal cadaver, whatever that presenting part may happen to be.

With these rubber cervices many conditions heretofore difficult of demonstration may be easily and readily made plain. The protrusion of the bag of waters (using the French rubber uterus for the membranes), the characteristics of the presenting part during the several stages of dilatation, the application of cervical dilators, or the performance of obstetric operations through a partially dilated cervix, as well as many other conditions, may be fully and clearly demonstrated.

Objection has been raised against the Schultze manikin that the pelvic floor is too hard and resisting, that there is no attempt to imitate nature in the construction of the vulva, that there is no vagina within the pelvis, and that, consequently, the Budin-Pinard manikin, which has none of these so-called objections, is to be preferred of the two.

For those who desire it, a rubber vulva and vagina may now be procured * which are somewhat similar to the same parts in the French manikin, and which may be attached to or removed from the Schultze manikin at will.

The manikin that the writer desires to present to the Section this evening is one which he believes more fully fulfills the requirements for obstetric teaching and demonstration than any other now in use.

The idea of producing an obstetric manikin in the shape of a complete human form, with movable joints that would permit of the figure being placed in any desired position, originated with Professor Theophilus Parvin, of Philadelphia, and it was at Dr. Parvin's suggestion that the writer undertook the production of the present manikin.

After considerable planning, directing, and supervising, suffice it to say that we obtained from a model-maker a life-sized figure, possessing a form proportioned with the nearest approach to nature possible.

In Figs. 9, 10, and 11 the manikin is seen in different postures.

The joints are mobile, so as to permit of all the various movements and to allow of the figure being placed in any desired posture—dorsal, lateral, semi-prone, or knee-chest. The pelvis is an exact reproduction in brass of the most perfect bony pelvis obtainable, and is completely and smoothly covered with soft leather, which leaves all the elevations and depressions of the original bony pelvis unchanged. This permits of the effect of these elevations and depressions upon the mechanism of labor being demonstrated, and of the various diameters and circumferences of the pelvis, external and internal, being measured with the pelvimeter. The coccyx is so arranged by means of a hinge and spring at the rear that it is movable to the extent of allowing recession of this bone one inch. A false sacrum is provided, controlled by a rod and thumb-screw in the lower dorsal region, by means of which any desired contraction of the conjugate diameter of the brim may be produced (Fig. 10).

Further, a soft leather pelvic floor is added, which readily allows the exit of the fœtus, or the use of instruments, palpation, or manual extraction, as desired (Fig. 10).

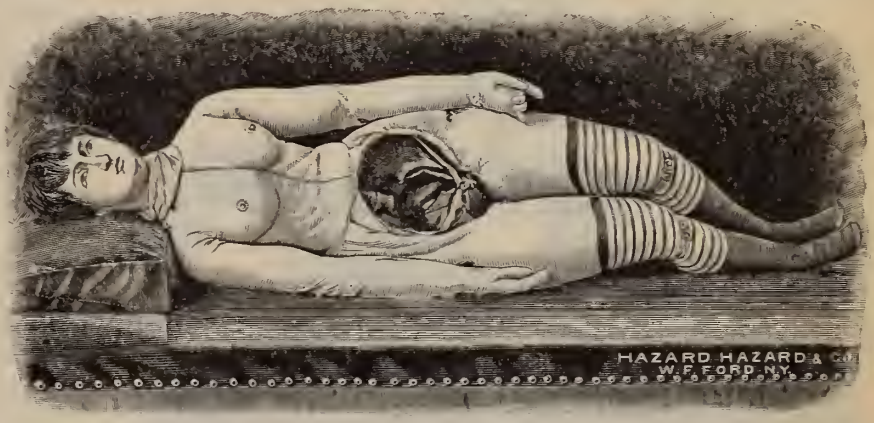

FIG. 9.—Manikin of Professor Theophilus Parvin and the writer.* Anterior view.

For the anterior abdominal wall, instead of the inflatable rubber covering of the Budin-Pinard manikin, which constantly needs replacing, a simple leather apron is provided, which experience has shown answers every purpose.

The joints are so made that a single bolt controlled by a key tightens or loosens them at pleasure. The abdominal cavity (Fig. 9) is made large enough to admit two fœtuses, if need be, or the rubber uterus of Winckel (Fig. 7) or of

* From Metzler & Co., 8 Kaufinger Strasse, Munich, Bavaria.

* Parvin-Edgar manikin.

the French school (Fig. 4), or both may with advantage be used.

The entire external surface of the manikin, with the exception of the head, is covered with soft leather; and the figure itself is light enough to be freely movable upon the operating table, or carried from place to place.

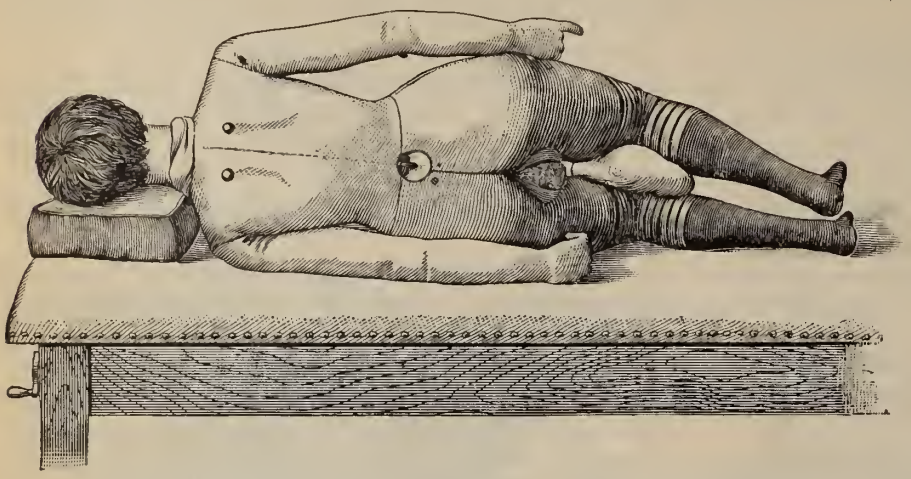

Fig. 10.—Manikin of Professor Theophilus Parvin and the writer. Left lateral posture. Head of fœtal cadaver seen distending the vulva.

Since we have in this obstetric manikin a complete human form, that may be placed in any desired posture (Figs. 9, 10, 11), that will permit of the application of any bandage, binder, or dressing, that possesses all the advantages, and few, if any, of the disadvantages, of the Budin-Pinard and Schultze manikins, it is the belief of the writer that the improved manikin contains the most desirable factors necessary for instruction and class-room demonstration.

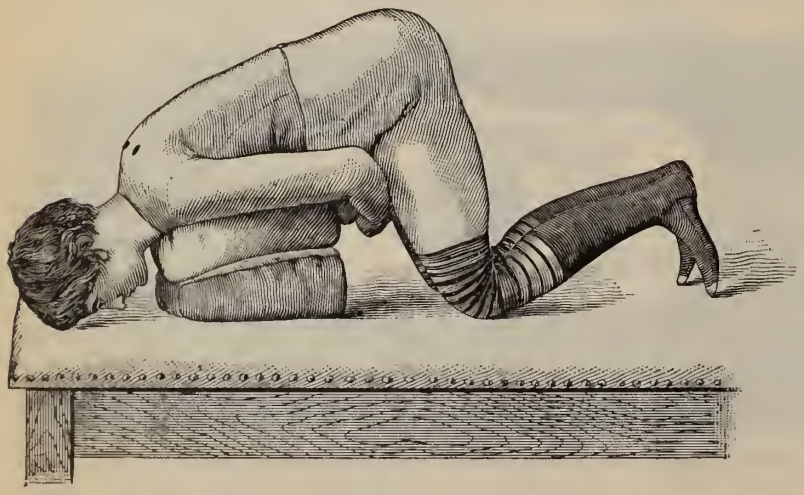

Fig. 11.—Manikin of Professor Theophilus Parvin and the writer. Knee-chest posture.

For demonstrating the mechanism of labor before a large class—the application of the forceps, cranioclast, cephalotribe, and other obstetric instruments; the various methods of performing version; the different methods of manual extraction, whether by the head, shoulders, breech, or lower extremities—the gun-metal pelvis, covered with leather and mounted upon a tripod, and devised by the writer of this paper, has proved itself exceedingly useful (Figs. 12, 13).

The pelvis is practically indestructible and is so mounted (Fig. 12) upon the upright of a tripod as to permit of rotation in an entire circle in a horizontal plane, and this permits the pelvic outlet or inlet being directed to any point desired.

Besides complete rotation in the plane of the horizon, partial rotation upon a transverse axis is also easily and quickly secured, and a simple device (Fig. 13) in the shape of a small wheel at the side enables one to fix the planes of the pelvis (represented by card-board if need be) at any desired angle with the horizon.

If desirable, for greater convenience and accuracy, a simple scale may be added at the side, which will enable one to read off at a glance the angle produced. A movable coccyx permits recession during the passage of the fœtus, and a spring throws it back again to its true position. A false sacrum, controlled by a thumb-screw passing through the true sacrum, enables one to illustrate contraction of the pelvis in its antero-posterior diameter, or to fix the presenting part of the puppe or fœtal cadaver in any desired position. With such material as the foregoing—the four manikins, with their several accessories, together with an abundant supply of fœtal cadavers of various sizes—there is scarcely an obstetric operation or procedure that may not be performed or demonstrated.

CONCLUSIONS.

1. Practice upon the obstetric manikin should supplement, not supplant, clinical instruction. The former should go hand in hand with instruction at the bedside.

2. Skill in determining the attitude, the various presentations and positions of the fœtus, by external and internal palpation, should be obtained by the student or practitioner before actually undertaking the care of a woman during confinement.

3. Familiarity with the construction and the application of the various obstetric instruments, as well as with the performance of each operation, should be acquired before subjecting the pregnant or parturient woman to these operative procedures.

4. Both of the foregoing—viz., skill in diagnosis and dexterity in operating—can undoubtedly be obtained by practice either upon the cadaver of a puerperal woman, together with the fœtal cadaver, or upon suitable manikins.

5. The recent improvements in obstetric manikins have rendered them more practical than, and quite as satisfactory as, the cadaver.

6. With the material at our command, there is scarcely

an obstetric procedure or operation that may not be demonstrated or performed.

III. *What may be accomplished with the Obstetric Manikin.*—With a view to showing those who are interested in midwifery what one is able to accomplish with the obstetric manikin in the matter of demonstration, practice, and operation, the writer of the foregoing paper has taken the liberty of appending to it his "*Scheme of Instruction*" that it has been his custom to follow for the past two years in his various sections and classes at the University Medical College of this city:

Fig. 12.—The writer's metal pelvis and tripod. Useful for demonstrating the mechanism of labor and obstetric operations.

WHAT MAY BE ACCOMPLISHED WITH THE OBSTETRIC MANIKIN.

DEMONSTRATIONS AND OPERATIONS.

A. Pregnancy.

I. *Abdominal Palpation :*

1. Location of the head, breech, shoulder, small parts, dorsal plane. 2. Attitude, presentation, and position of the fœtus (normal, abnormal). 3. Abdominal ballottement; fluctuation. 4. Diagnosis of twins, triplets. 5. Height of fundus.

II. *Vaginal Palpation ; Rectal Palpation :*

1. Internal ballottement. 2. Diagnosis of vertex, breech, face, brow, and shoulder presentations. 3. Diagnosis of vertex, breech, face, brow, and shoulder positions.

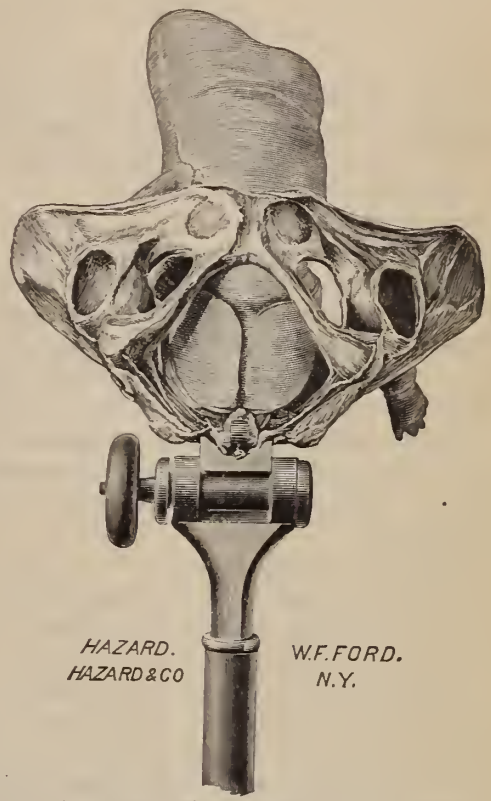

Fig. 13.—The writer's metal pelvis and tripod, showing head of puppe at pelvic outlet.

4. Height of presenting part in pelvis. 5. Conjugata diagonalis; conjugata vera. 6. Antero-posterior diameter of outlet; distance between spines of ischii.

III. *Conjoined Palpation :*

1. Abdomino-vaginal. 2. Abdomino-rectal. 3. Vagino-rectal. 4. Abdomino-recto-vaginal.

B. Labor.

I. *False Pelvis ; True Pelvis :*

1. Inlet. 2. Cavity. 3. Outlet. 4. Planes. 5. Axes. 6. Angles. 7. Diameters. 8. Circumferences.

II. *Characteristics of Fœtal Head and Body :*

1. Shape. 2. Movements. 3. Compressibility. 4. Diameters. 5. Circumferences. 6. Fontanelles. 7. Sutures.

III. *Attitude ; Presentation ; Position.*

IV. *Classification of Presentations.*

V. *Characteristics of Vertex, Breech, Face, Brow, Shoulder, Trunk, Ear, Hand, Elbow, Foot, Knee, Mouth, Anus, Genitals.*

VI. *Mechanism of Labor :*

1. Vertex. 2. Breech. 3. Face. 4. Brow. 5. Shoulder. 6. Occipito-posterior positions. 7. Mento-posterior positions. 8. After-coming head. 9. Doubled fœtus. 10. Spontaneous version. 11. Spontaneous evolution. 12. Lateral obliquity of head (Nägele). 13. Placental delivery (Schultze, Duncan).

VII. *Management of Labor:*

1. Preparation of labor-bed. 2. Posture of parturient during several stages. 3. Effect of posture of woman upon presentation. 4. Treatment of second stage. 5. Method of following down the fundus. 6. Protection of perinæum (various methods). 7. Management of the funis about the neck. 8. Delivery of shoulders and trunk. 9. Ligature of the funis; care of child; various methods for grasping and holding the child. 10. Treatment of third stage. 11. Abdominal binder. 12. Vulva pad. 13. Breast binders.

VIII. *Asphyxia Neonatorum:*

1. Rapid delivery (various methods). 2. Removal of foreign substances from air passages: *a*, inversion of child; *b*, mouth-to-mouth method; *c*, use of gauze; *d*, catheter; *e*, various aspirators. 3. Restoration of respiration: (1) Reflex stimuli (various); (2) artificial respiration: *a*, mouth to mouth; *b*, catheter; *c*, Ribemont-Dessaignes insufflator; *d*, aspirator of Jawisch; *e*, Sylvester method; *f*, Schultze method; *g*, Marshall Hall's method; *h*, Byrd's method; *i*, faradization; *j*, gavage.

IX. *Hæmorrhages:*

1. Accidental Hæmorrhage:
(1) Varieties; (2) ætiology; (3) diagnosis; (4) prognosis; (5) treatment: *a*, tampon; *b*, Barnes's bags; *c*, vaginal colpeurynter.

2. Unavoidable Hæmorrhage; Placenta Prævia:
(1) Varieties; (2) ætiology; (3) diagnosis by palpation; (4) prognosis; (5) treatment: *a*, tampon; *b*, Barnes's bags; *c*, vaginal colpeurynter; *d*, Barnes's method; *e*, Cohen-Credé method; *f*, Simpson's method; *g*, Pfeiffer's method; *h*, rapid delivery.

3. Post-partum Hæmorrhage:
(1) Varieties; (2) ætiology; (3) diagnosis by palpation; (4) prognosis; (5) treatment: *a*, simple compression; *b*, Breisky's method; *c*, Gooch's method; *d*, intra-uterine applications (heat, styptics, packing with gauze); *e*, faradization.

X. *Pelvic Deformity:*

1. Varieties. 2. Ætiology. 3. Diagnosis: *a*, Pelvimetry, external and internal; *b*, manual pelvimetry. 4. Prognosis. 5. Treatment: *a*, induction of abortion; *b*, induction of premature labor; *c*, forceps; *d*, version; *e*, advantages and disadvantages of forceps and version; *f*, choice between forceps and version; *g*, embryotomy; *h*, Cæsarean section.

XI. *Prescntation and Prolapse of the Cord:*

Definitions; Frequency; Ætiology; Symptoms; Diagnosis; Prognosis.

Treatment: *a*, postural reposition; *b*, manual reposition; *c*, instrumental reposition; *d*, rapid delivery of fœtus.

XII. *Rctcntion of the Placenta:*

Treatment: *a*, Credé's method of expression; *b*, manual extraction.

C. Obstetric Operations.

Operations performed during Pregnancy.

I. *Induction of Abortion:*

1. Bougie. 2. Cervical dilators.

II. *Induction of Premature Labor:*

1. Bougie. 2. Cervical dilators. 3. Gavage. 4. Couveuse.

Operations performed during Labor.

I. *Expression of the Fœtus—Expressio Fœtus.*

II. *Forcible Delivery—Accouchement forcé.*

III. *Manual Extraction of Head (Ritgen's Method).*

IV. *Extraction in Pelvic Presentations:*

1. Expressio fœtus. 2. Traction with finger. 3. Manual extraction: *a*, Winckel's method; *b*, A. Mar's method. 4. Blunt hook. 5. Fillet: *a*, single sling; *b*, Galabin's double sling. 6. Traction on one or both legs. 7. Forceps.

V. *Extraction of After-coming Head:*

1. Manual rotation of transversely-placed head. 2. Delivery of arms (Winckel's method, Barnes's method). 3. Methods of Smellie, Veit, Mauriceau (Veit-Smellie). 4. Wigand—A. Martin's method. 5. Prague method. 6. Forceps.

VI. *Forceps:*

1. Actions (5). 2. Indications. 3. Conditions necessary. 4. Dangers (fœtus, mother). 5. Varieties: *a*, long; *b*, short; *c*, straight; *d*, axis-traction (Tarnier, Breus, Hubert, Albert H. Smith method). 6. Operations: *a*, low; *b*, high; *c*, axis-traction; *d*, *adaptation of the forceps*; *e*, vertex presentations (anterior positions); *f*, face presentations (mento-anterior positions); *g*, pelvic presentations; *h*, occipito-posterior positions; *i*, mento-posterior positions; *j*, incomplete flexion of head; *k*, incomplete extension of head: *l*, after-coming head; *m*, use of dynamometer.

VII. *Version:*

1. Varieties: *a*, cephalic; *b*, pelvic; *c*, podalic. 2. Methods: *a*, postural; *b*, external; *c*, internal; *d*, combined. 3. Description; conditions necessary; indications; contra-indications; dangers; time for operating; preparation; position of parturient; choice of hands; choice of part to be seized; instruments. 4. Postural version. 5. External version. 6. Combined version (external and internal): *a*, Hohl's method; *b*, Braxton-Hicks's (Wright's) method. 7. Internal cephalic version: *a*, D'Outrepont's method; *b*, Busch's method; *c*, Vienna method. 8. Internal podalic version: *a*, in cephalic presentations; *b*, in shoulder presentations. 9. Internal podalic version in impacted shoulder presentations: *a*, position of parturient; *b*, choice of hand for operating; *c*, use of sling to prolapsed arm; *d*, choice of leg to be seized (upper or lower, one or both, knee or foot); *e*, blunt hook; *f*, sling to leg; *g*, Foster's method when the arm is prolapsed. 10. Combined postural (knee-chest), internal and external, cephalic or podalic version in shoulder presentations.

VIII. *Rectification of Face and Brow Presentations:*

1. Schatz's method. 2. Playfair, Humphrey-Partridge method. 3. Fillet. 4. Breus's forceps. 5. Baudelocque's method.

IX. *Treatment of Mento-posterior Positions:*

1. Extreme extension of head: *a*, position of parturient; *b*, hand; *c*, Breus's forceps. 2. Resistance supplied: *a*, hand; *b*, blade of forceps; *c*, vectis. 3. Straight forceps. 4. Ordinary forceps. 5. Version. 6. Perforation; extraction.

X. *Treatment of Occipito-posterior Positions:*

1. Extreme flexion of head: *a*, position of parturient; *b*, hand; *c*, Breus's forceps. 2. Resistance supplied: *a*, hand; *b*, blade of forceps; *c*, vectis. 3. Straight forceps. 4. Ordinary forceps. 5. Version. 6. Perforation; extraction.

XI. *Treatment of Difficult Shoulder Delivery in Head-first Cases:*

1. Expressio fœtus. 2. Traction on posterior shoulder. 3. Rotary motion with head. 4. Traction on both shoulders (Winckel's method). 5. Pushing anterior shoulder behind symphysis. 6. Use of blunt hook.

XII. *Embryotomy:*

1. *Perforation; Craniotomy.*

Definition; Object; Indications; Conditions necessary; Dangers.

(1) Advantages and disadvantages of the cranioclast. (2) Perforation accomplished by: *a*, knife; *b*, scissors; *c*, trephine. (3) Extraction or expulsion accomplished by: *a*, crotchet; *b*, hand; *c*, bone forceps (craniotomy forceps); *d*, cranioclast (Brann's); *e*, cephalotribe (Breisky's, Lusk's); *f*, obstetric forceps; *g*, version; *h*, uterine forces; *i*, expressio fœtus. (4) Perforation of after-coming head.

2. *Cephalotripsy, before and after Perforation.*

Definition; Object; Indications; Conditions necessary; Dangers.

(1) Advantages and disadvantages of the cephalotribe. (2) Crushing accomplished by: *a*, cephalotribe; or *b*, cranioclast and cephalotribe. (3) Extraction or expulsion accomplished by: *a*, cephalotribe; *b*, cranioclast; *c*, obstetric forceps; *d*, crotchet; *e*, hand; *f*, bone forceps; *g*, uterine forces; *h*, expressio fœtus.

3. *Decapitation.*

Definition; Object; Indications; Conditions necessary; Dangers.

(1) Decapitation accomplished by: *a*, Braun's hook; *b*, Schultze's sickle knife; *c*, silk sling and scalpel; *d*, whip-lash (Pajot); *e*, wire écraseur; *f*, chain saw; *g*, ordinary scissors; *h*, Dubois's scissors. (2) Extraction of body: *a*, manual; *b*, instrumental. (3) Extraction of head: *a*, manual; *b*, instrumental.

4. *Evisceration.*

Definition; Object; Indications; Conditions necessary; Dangers.

(1) Perforation: *a*, knife; *b*, scissors; *c*, trephine. (2) Extraction: *a*, manual; *b*, instrumental.

5. *Amputation of Extremities.*

XIII. *Improved Cæsarean Section:*

Definition; Object; Indications; Conditions necessary; Dangers.

1. Operation (manikin).

XIV. *Porro's Operation:*

Definition; Object; Indications; Conditions necessary; Dangers.

1. Operation (manikin).

115 East Thirty-fifth Street.

THE CLINICAL ASPECTS OF KOCH'S METHOD IN BERLIN.

By HENRY S. STEARNS, M. D.

When at the last International Medical Congress, held in Berlin, Professor Robert Koch gave a few hints in regard to his investigations on tuberculosis, great anxiety was evinced by the entire profession to have his results made public as soon as possible. There is no doubt, however, that any formal statement would not have been made had it not been for the sensationalism thrown around the matter and the false impressions being given of it by the public press. To correct this state of affairs he was compelled to publish, on November 13th, in the *Deutsche medicinische Wochenschrift*, his now historical article entitled Mittheilungen über ein Heilmittel gegen Tuberculose. This was immediately translated and published in this country, and, instead of allaying excitement, raised it to a still higher pitch, which culminated in the emigration to Berlin of quite a number of physicians from different parts of this country, their primary object being, of course, to gain possession of some of the famous "lymph," and after that to study the clinical aspects of the treatment.

By the courtesy of Professor Leyden and Professor von Bergmann I was enabled to go into the hospital wards at almost any hour and to watch closely several of the most interesting cases. The form of tuberculosis showing the most incontrovertible evidences of the value of the inoculations or injections is lupus. A large part of Professor von Bergmann's private hospital is given over now to the treatment of lupus patients, and, without a single exception, results are there seen which six months ago would have been beyond a specialist's most enthusiastic hopes.

A most interesting case was that of a young Englishman whose treatment had been completed before I left Berlin. He was twenty-two years of age, and the disease was of six years duration, growing steadily worse in spite of between forty and fifty curettings and cauterizations, several of the operations having been severe enough to require the administration of an anæsthetic, until both alæ of the nose were destroyed, together with a portion of the septum and a small part of the cheek. There was an ulcer on the left cheek 1·5 ctm. in diameter, the septum was perforated, suppurating glands at the right angle of the jaw underlay lupus patches, and other small patches had made their appearance on the gums, hard palate, tonsils, and uvula. He suffered no pain and had no pulmonary infection.

While the general course of the disease had been from bad to worse, still he had noticed that when his general health improved temporarily there would at the same time be a very slight improvement in the sores. The treatment was begun on November 16th with an injection of 0·01 c. c. of the lymph, at 8 A. M. In about seven hours he was seized with a rather severe chill, intense headache, rapid gasping breathing, and fever, which by 11 P. M. had risen to 104·2° F. The temperature re-

mained at this height for only half an hour, and then fell with sharp variations to normal by the evening of the next day. By 3 P. M. on the day of the injection all of the lupus patches had become swollen, intensely congested, and painful, and had, as he described it, a yellowish pustule form over each one. This appearance was changed in twenty-four hours by the drying up of the pustules and the formation of a scab, the redness, swelling, and pain also gradually disappearing as the temperature fell. At no time subsequent to the first injection was there any chill, and after each succeeding injection the pain, redness, swelling, and temperature were less than during the reaction of the preceding one. The duration of the treatment was eighteen days, in which time the patient received fifteen injections, the quantity being gradually increased to 0 1 c. c. On the eighteenth day of the treatment all the lupus patches were completely healed over; the right nostril was closed to such an extent that only an ordinary-sized probe could be passed through, but the opening of the left nostril was large enough to do duty for both sides. The ulcer on the septum had healed, but of course the perforation remained. The ulcer on the left cheek had a glazed appearance, and wherever the lupus had existed the healed spots were still somewhat red, resembling a fresh cicatrix. The fauces, tonsils, hard palate, and uvula showed only an intense redness.

This case was elected out of a number placed at my disposal by Dr. De Ruyter, first assistant to Professor von Bergmann, as being as nearly as possible a typical one, and showing how even increasing doses caused less and less reaction as the tuberculous tissue was gradually destroyed. In ten cases the reaction began in from four to eight hours after the injection, remained at its height ordinarily less than an hour, and had in the majority of cases entirely disappeared in twenty-four hours. A very interesting feature in one of these cases was the intense pain felt in a hip joint that had been the seat of tubercular arthritis for nine years, but for the last fourteen years had given no sign of trouble. In two other cases enlarged glands at the angle of the jaw and in the neck swelled and became very painful during the reactions. In another case a curious eruption made its appearance, principally on the legs. This at first consisted of moderately red spots about 1 ctm. in diameter, sharply outlined and very slightly elevated above the surface. In a few days these became of a dull copper color and remained so as long as the patient was under my observation. In every case of lupus seen the cure of the infected areas was either progressing rapidly or was entirely completed. Of course it is too soon to say how permanent these cures are, but if the lupus returns in time we have here a therapeutic resource by which the frightfully disfiguring effects of this disease can be permanently held in check by subsequent injections, and if there was no other use to which the "lymph" could be put it would still be one of the most important additions to therapeutics received in a great many years. But that it has other and far more important applications is alleged for it by its discoverer, and these are: 1. The cure of tuberculous disease when seated internally as well as externally. 2. Almost invariable ability to diagnosticate the presence of tubercular disease wherever situated.

As regards the first of these allegations, there was nothing seen during my stay in Berlin which would warrant the assertion that internal tuberculosis could be cured by this method, unless it might be the more or less logical deduction from the results gained in lupus and in tuberculous ulcers of the larynx. But at the same time it must be borne in mind that a cure of pulmonary tuberculosis would of necessity be a more prolonged process than in external cases, where the necrotic tissue can be immediately thrown off, and in none of the cases seen had the treatment been carried on long enough to say authoritatively whether much benefit would result from it or not. On the contrary, in a ward of thirty-six beds, with twenty-seven patients undergoing the treatment, there were only two whose weight had increased, most of the others having remained stationary or having lost from one to two kilogrammes, and, besides that, there was in nearly every case a decidedly worse condition, as shown by the physical signs. This condition, however, it is maintained, is due to the necrotic changes caused by the treatment, and is a necessary preliminary to the final cure. Whether this is the case or not, only a much more extended experience with the remedy will show.

To cite one instance of the possible detrimental effects of the remedy, the case may be mentioned of a man who was admitted into the Charité Hospital on November 21st.

He was suffering from the effects of a pleurisy on the left side, contracted seven months before, when he had had removed by aspiration four litres of sero-fibrinous fluid from the left pleural cavity. Since then he had been steadily losing flesh and strength. On admission he was rather emaciated, but had no cough and no fever. The left side of the chest was markedly depressed, measurement showing a difference of 4 ctm. in favor of the right side. The respiratory movement on the left side was almost imperceptible, and, on auscultation, a few rough friction sounds were audible over the lower half of the lung on that side. On November 23d the first injection was given, for diagnostic purposes, 0·003 c. c. being the amount used. The temperature rose in ten hours to 103°, with all the usual effects of reaction, such as severe headache, slight chill, and pains in the bones, and in this case there was a rather severe pain on the left side of the chest over the seat of the old pleurisy. On November 25th the second injection, of the same amount of the "lymph," was given, and the temperature only rose to 100·2°. Cough now made its appearance, and, on examination, the sputum was found to contain tubercle bacilli, which of course confirmed the diagnosis of tuberculosis. On November 26th the third injection was given, the amount this time being 0·006 c. c. Moderate reaction resulted, and the cough was very severe until this had subsided. On November 28th the fourth injection was given, the amount being 0·01 c. c. The temperature rose to 102·2°. On November 29th the patient showed a loss of two kilogrammes in weight, and, besides, a number of moist friction sounds had made their appearance at the base of the left lung, being most marked anteriorly. On November 30th the fifth injection, the same in amount as the last, was given with no decided reaction. On December 2d the sixth injection was given, the quantity being 0·02 c. c. The temperature rose to 101·6°, and the whole front of the chest gave loud, moist friction sounds. On December 4th physical examination of the chest revealed the presence of a moderate effusion in the left pleural cavity, and on the last day I saw the patient. On December 6th the level of the fluid was slightly above the angle of the scapula.

In another case, in which there was a moderately large spot of consolidation in the upper lobe of the right lung,

with tubercle bacilli in the sputum, under the treatment a portion of the consolidated area softened rapidly and a cavity was formed.

These results at first appear very discouraging and decidedly dangerous, but it must be remembered that, if we are to accept Koch's explanation of what he believes to be the pathological changes caused by his treatment, the above-mentioned effects are exactly what must make their appearance before the cure can go on to completion, and, besides, the duration of the treatment in these cases is too short to more than carry the patient well on into what may be termed the first stage of the cure. What the succeeding stages will be no man to my knowledge can state authoritatively. We can only trust that the future will bear out the discoverer's statements, and bear in mind that after all tubercular tissue has become necrotic it should be quickly got rid of, where possible, by surgical interference. In cases of phthisis this process will necessarily be a slow one, and in these cases there is great danger of further infection, as the bacilli are not destroyed; to use Koch's own words, "The endangered living tissue must be protected from fresh incursions of the parasites by continuous applications of the remedy."

In the use of the "lymph" a point always requiring the most anxious consideration is the more immediate dangers. These arise from two of the results of the inoculations: 1. Necrotic changes. Here it is apparent that where there are tubercular ulcers of the intestines it is entirely within the bounds of possibility that perforation and fatal peritonitis may occur, and there has already been a death in Berlin from this cause. 2. The swelling of the infected tissue may seriously menace life, and several tracheotomies have already been required where tubercular ulcers of the larynx were present, the swelling so nearly closing the rima glottidis that without prompt surgical interference the patients would have died from suffocation.

There can be no doubt that we have in this "lymph" a most powerful agent and a very dangerous one as well, when used carelessly, but there would seem to be no reason why in careful and competent hands it should not do an inestimable amount of good, more particularly in laryngeal tuberculosis, lupus, and tuberculous joint diseases. That it will give as beneficial results in the early stages of phthisis there would seem to be great possibility, but when cases of advanced phthisis come under consideration it may be seriously doubted whether it would be advisable to subject the patients to the decided dangers that must accompany its use, at least by the present method, where the agent is used in ever-increasing doses in order that the reaction may be as marked as possible. Perhaps it may be found advisable in these advanced cases to use smaller doses, thereby making the treatment slower but far safer.

A few words as to the method of administration as followed in Berlin. The usual dose to begin with in lupus cases with no apparent pulmonary or laryngeal complications is 0·01 c. c., and in phthisis from 0·001 to 0·003 c. c. As soon as the reaction has ceased and the temperature returned to normal, or nearly so, the same or only a slightly increased amount is again injected, and this plan is followed until the temperature fails to rise above 101°, when the dose is usually doubled, and so on, until in some cases as high a dose as 0·1 c. c. is reached. This amount, however, is exceptional; I have seen it used only once, and then it was the final injection in the case of lupus cited above and gave absolutely no reaction. Ordinarily 0·04 c. c. would be considered a large dose, even if the treatment was well advanced.

HYDROGEN DIOXIDE; A RÉSUMÉ.

By JOHN AULDE, M. D.,
PHILADELPHIA,
MEMBER OF THE AMERICAN MEDICAL ASSOCIATION,
OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA,
OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY, ETC.

Within the past ten years the use of hydrogen dioxide (peroxide of hydrogen) has become quite general among practitioners whose business has led them to give special attention to some particular class of disorders. Many general practitioners, however, have not availed themselves of the benefits afforded by this comparatively recent addition to our therapeutic resources, owing to the expense and the care required in looking after details, together with the uncertainty which attended its employment. These difficulties no longer exist; but, when we consider the advantages to be gained from its use, the process of evolution has been remarkably slow, notwithstanding the sporadic attempts which have been made to attract the attention of the medical profession. Novel methods of treatment are too frequently shunned without investigation by regular physicians, while, on the contrary, these innovations are readily adapted to the wants of the quack.

In the present instance, although the *furore* for antiseptics continues unabated, the true position of oxygen has been ignored by those who should have given it their first attention. Long-continued and persistent effort has erected an imposing superstructure upon a theoretical foundation, losing sight of the marvelous influences constantly at work in nature. The corner-stone of this ornate edifice originally adopted was carbolic acid; the pilasters which gave strength and beauty to its walls were composed of carbolated gauze, while cornice and roof were made of protective which had been submitted to a carbolizing process. This highly flavored substance has given place to a number of others, some of which are safer, but no more useful; others are more efficient than carbolic acid, but, as usually employed, are far more dangerous. As the foundation for asepsis rests upon absolute cleanliness, so the foundation for antisepsis must rest upon an equally safe basis as regards the patient. The only agent known at the present time which fully meets our requirements is oxygen in some of its forms. While the spores of anthrax bacilli resist our most poisonous products—such as solutions of hydrochloric acid (two per cent.), boric and salicylic acids in concentrated solutions—oxygenated water alone, in sufficient quantity, was shown by Paul Bert and Regnard to possess the power of destroying the bacteria.

The wonderful properties of ozone are but partly understood; like some other powerful agents, it can not be safely

handled, but it gives great promise of usefulness in the future. The statement has been made that ozone is but an allotropic form of oxygen, and that it is identical with hydrogen dioxide (the subject of the present article), and for all practical purposes, from a therapeutic standpoint, they may be considered substantially the same. Having, then, at our command a remedy possessing such remarkable properties as a bactericide, one which is perfectly harmless when brought into contact with healthy tissues, it will be worth while to study the indications for its use in the treatment of disease. In the first place, however, I should say a word with reference to the causes which have contributed to prevent its universal employment by physicians—causes already referred to incidentally.

1. *The expense* of an outfit and material for administration of this agent need not exceed five dollars for sufficient to cover a period of from six weeks to two months. The medicinal peroxide can be purchased in original packages at about the cost of filling a prescription at a first-class drug-store. An atomizer and vaporizer combined, especially required for this substance, costs no more than one equally complete for ordinary use.

2. *The inconveniences* attending the exhibition of hydrogen dioxide, by means of the vapor or spray, are purely imaginary. The use of these instruments by patients requires but little manual dexterity, and the instructions in regard to inhalations may be comprehended by the merest tyro. Children rather enjoy the mechanical features of the apparatus with the novel phenomenon of having the vapor expelled through the nostrils.

3. *The uncertainty* following the employment of the peroxide has arisen from various causes, and, as this is a subject of paramount importance, the items will be considered in detail. In the pure state hydrogen peroxide is exceedingly unstable, and, in order to render it less susceptible to the action of heat, which causes it to part with nascent oxygen rapidly, minute quantities of hydrochloric and phosphoric acids are added to the usual fifteen-volume solution; but this, instead of retarding, rather heightens the effect of the remedy when applied to unhealthy structures, especially mucous surfaces. When the container is allowed to remain in a warm room, or when it is not properly stoppered, the activity of the preparation is materially lessened, if not entirely lost. An excess of acid is objectionable, however, as it renders the peroxide irritating instead of soothing.

Commercial peroxide, which is used extensively for bleaching purposes and in the arts, is doubtless responsible for unsatisfactory results, but, as compared with the medicinal preparation, it is a very inferior product, sold at a cost of about eight cents a pound. Physicians should know that this product always contains a large proportion of acids (two to five per cent.), hydrofluoric, sulphuric, hydrochloric, oxalic, and nitric acids, and, knowing this to be the case, they should be careful to examine the reactions and see that the medicinal preparation obtained by patients is supplied in original packages. The commercial product is not "just as good" nor will it "do as well" for the patient; and if these suggestions are kept in view, the success of the peroxide is assured.

Another important thing which I have learned is, that the mixture of the peroxide with glycerin does not make "glycozone," but, instead, a mixture which generates slowly but constantly secondary products, which appear to possess irritating properties almost as toxic as those of formic acid, well known in Central Africa as a deadly arrow-poison. I am of the opinion also that when the peroxide is used in the form of an inhalation by heating with water, a considerable proportion of the nascent oxygen is transformed into ordinary oxygen before reaching the affected tissues, and while I can readily understand how this must detract from its efficiency, remarkably prompt results have attended its administration in this manner. The only obstacle in the way of securing immediate and favorable results from the exhibition of this agent is our inability to command at all times a freshly prepared and thoroughly reliable product, free from the impurities incident to its manufacture; but that difficulty, I believe, is no longer an excuse, as it can be supplied by the principal druggists throughout the country.

Pharmacology.—In order to estimate with some degree of accuracy the ultimate changes effected in living tissues from the employment of oxygen, and especially nascent oxygen, our study must embrace a recapitulation of the metamorphoses taking place in the protoplasm. This seems all the more necessary for the purpose of meeting objections which have been urged against the use of oxygen, owing to the supposed dangers of hyperoxygenation and a consequent increased rapidity of combustion, although these notions are altogether fanciful. Alkalinity of the blood enhances the oxygen-carrying capacity of the red corpuscles; hence the utility of alkaline mineral waters, which increase cell-activity. Ehrlich has shown that the function of the cell is to generate acid products of tissue-waste; but when these waste products accumulate, cell function is diminished or arrested, no more combustion taking place until acid products are removed or neutralized, thus indicating that we have to deal with a species of cell-automatism. Another significant question presents itself in this connection, viz., If increased alkalinity of the blood favors oxidation, how does it happen that the cell is not entirely consumed? This is explained by Ehrlich on the assumption that all protoplasm is enveloped by cell-juice (paraplasm), which expands or contracts in proportion to the demand of the cell for oxygen. Contraction of the cell takes place when there is no demand for oxygen, and at the same moment the increased thickness of the paraplasm prevents the absorption of oxygen. Alternate contraction and distention of the cell affects the thickness of the layer of cell-juice, and increases or decreases cell combustion; in other words, it prevents the too rapid oxidation of protoplasm.

In the light of the foregoing demonstration there can be no hesitancy in ascribing the therapeutical value of oxygen, in whatever form employed, to its influence upon cell activity. The entire organism being composed of cells, the conclusion is inevitable that all agents which increase the normal function of the cell increase in like manner the resistance of the organism to the inroads of disease. This is

further exemplified by the active oxidation (combustion) which takes place when the peroxide is brought into contact with unhealthy tissues, and still no deleterious action is noticeable upon the normal structures, a statement of fact which can be applied to no other known antiseptic. Pus and all other unhealthy discharges are promptly destroyed, the affected structures being left clean and perfectly free from micro-organisms.

Therapeutics.—From the peroxide of hydrogen we may obtain, in the form of a vapor or spray, the therapeutic effects of nascent oxygen, and as a surgical application or antibacterial substance this product is far superior to the gas itself. Used in the form of a vapor by inhalation, it increases the secondary assimilation by favoring the elimination of excrementitious products through the stimulating effect upon internal respiration. Just as pure mountain air arouses the activity of functions which have been depressed and promotes health, so oxygen evolved in this manner increases tissue change and prevents the suboxidation which attends upon the arrest of cell function. Oxygen is a tissue-builder as well as an oxidizer of carbonaceous and excrementitious products. When it is introduced into the alimentary tract, abdominal fermentations are arrested by the destruction of the germs which produce them; unhealthy mucous secretions are destroyed, while the vitality of the cells lining the walls of the intestine is augmented, and their power against the absorption of ptomaines and leucomaines greatly increased. The surgeon will find the peroxide an efficient and most convenient antiseptic, as it can be freely used in cavities, in discharging sinuses, and upon the most delicate tissues, without danger of producing the slightest irritation. In all cases of threatened collapse, in low conditions of the system, and during convalescence from severe illness, the physician should bear in mind the wonderful revitalizing properties of this remedy. Perhaps the reader will gain a more practical idea of the applications by a reference to some of the more prominent indications, and I shall briefly pass in review some of the diseases in which it may be used with beneficial results.

In *anæmia and chlorosis*, along with suitable diet and exercise as adjuvants, the inhalations will prove most valuable; appetite increases, digestion improves, and there is a marked change for the better in the appearance and in strength. The feeling of *malaise* disappears within a few days after beginning treatment, listlessness is banished, and the patient takes an active interest in amusements which require considerable exercise, and seemingly with the greatest zest. *Erysipelas* is a disease in which the vapor may be used internally and the spray locally, apparently with the best results, as the progress of the disease is arrested by destroying the germs, increased resistance being given at the same time to the organism. In *septicæmia*, along with diffusible stimulants and suitable vascular tonics, it will be found an efficient adjuvant, and whenever it can be used locally in this affection the results will be brilliant indeed. *Lithæmia*, accompanied by cough, highly acid urine, with large quantities of uric acid and a diminution of the normal urea, is quickly benefited by the exhibition of the vapor. It is also a valuable adjuvant in the treatment of *rheumatism*, but with it should be combined the liberal use of alkaline waters, a judiciously selected dietary, and appropriate medication. It is also of decided benefit in the treatment of *diabetes mellitus* and in *albuminuria*, when it may be presumed to have some active influence in eliminating morbid products.

Since it has been determined that in *yellow fever* and *cholera* the poison germ is found only in the intestine, the peroxide promises to afford exceptional relief in these diseases. When it is introduced into the rectum, the heat of the body will cause oxygen gas to be evolved, while the local action of the drug will destroy all unhealthy products which may be present in the lower bowel. The nascent oxygen will be taken up by the absorbent structures and enter the general circulation; but if we accept the doctrine of phagocytosis, it will do even more than this, by reason of its stimulating action upon the modified white corpuscles, which are now regarded as the special enemies of bacteria escaping through the walls of the intestines. And for the same reason it may be used with advantage as a lavement in the treatment of *diarrhœa*, dysentery, and in typhoid fever. In the latter disease I have used the pure oxygen gas with very great satisfaction, and have found a solution of the peroxide superior as a mouth wash during the progress of this most tedious disorder.

The peroxide should be used in all forms of *indigestion*, more especially when the stomach is weak and depressed to such an extent that the usual antiseptics are not well tolerated. Those who use it once for the relief of indigestion, gastritis, gastralgia, and for the arrest of fermentation or an abnormal flow of mucus, will have no cause to regret the selection. A large number of *cutaneous affections* are dependent upon an unhealthy condition of the alimentary tract, such as urticaria, eczema, etc., and, of course, are benefited by the use of the peroxide.

Pulmonary affections have long claimed the attention of those who dabbled with oxygen inhalations, and it is in this class of cases where faithful attention to details will produce most marked effects, although I can not be convinced that any medicament in itself can arrest the progress of the disease. The continued use of the peroxide internally improves the primary assimilation; the regular and systematic inhalation of the vapor will not only improve the secondary assimilation, but will also destroy any morbid products with which it comes into contact in the pulmonary tissues, and, judging from my own experience with this agent, I have no hesitancy in saying that its value is not yet appreciated by a large number of physicians who, with it, might be the means of prolonging human life. My observations with the vapor and spray in *asthmatic conditions* have been surprising, and I have found them of signal service in meeting emergencies, such as asphyxia from coal gas, sudden collapse from hæmorrhage, typhoid, and other fevers. The long-continued use of the vapor has a marked effect in restoring the resiliency of the air-vesicles in *emphysema* when it occurs along with asthma in young persons. A gentlemen now under treatment has suffered from asthma since he was six weeks old, and is now twenty-five, but under this treatment he has gained weight, is able to

sleep regularly every night, and has increased sixteen pounds in weight during the past three weeks, while the chest measurement has appreciably decreased. This method of treatment is valuable in *phthisis* at all stages, but it should be used as an adjuvant to other treatment and attention given to diet. In this connection should be mentioned the usefulness of the vapor in the treatment of *bronchitis*, subacute and chronic, and at the same time the value in aborting attacks of acute catarrh.

Inhalations of the vapor will prove useful as an adjuvant in neuralgia, anæmic headaches, general debility, malarial toxæmia, and corpulence, combined with diet adapted to the various disorders mentioned.

In *surgical practice*, when the solution of the proper strength is brought into contact with diseased tissues, a brisk effervescence takes place and continues until all the pus-corpuscles present are destroyed. This solution may be used topically in nearly all cases of catarrh of the upper air-passages in the form of a spray, and it may be used as an antiseptic after the removal of pus in *empyema*. The substance possesses the advantage over other antiseptics of being harmless, and can therefore be used freely in *diphtheria* and *croup*. There are so many indications for its employment that it would be difficult to mention all the *topical uses*, although the following may be referred to, viz., boils, carbuncles, indolent ulcers, carcinoma, and venereal diseases as an injection.

The gynæcologist will find numerous applications for this agent. It may be used in the form of a douche in leucorrhœa, elytritis, and vaginismus, and a cotton-wool tampon may be saturated with it and placed in a gelatin capsule (veterinary size) and introduced into the vagina in the case of ulceration, vesico-vaginal fistula, and endometritis. The ophthalmologist and aurist will likewise find that it furnishes them the most complete and safe antiseptic that can be had, and gradually its employment will extend to every department of medicine and surgery.

The most flattering commendations of "Marchand's peroxide of hydrogen (medicinal)" have been given voluntarily by numerous well-known authors and contributors to medical literature within the past few years, some of whom may be mentioned as additional evidence that the methods here recommended are worthy of further investigation: Dr. W. B. Clarke, of Indianapolis, Ind.; Dr. George B. Hope, Surgeon to the Metropolitan Throat Hospital, New York; Dr. J. Mount Bleyer, of New York; Dr. Robert T. Morris, of New York; Dr. Paul Gibier, Director of the New York Pasteur Institute; Dr. R. Charest, of St. Cloud, Minn.; Dr. E. R. Squibb, of Brooklyn, N. Y.; and others whose names can not now be recalled. Dr. Morris refers to it as "the necessary peroxide of hydrogen," and I have found Marchand's product to possess in a remarkable degree the properties so essential to success — viz., uniformity in strength, purity, and stability.

1910 Arch Street.

A Case of Acromegaly, the first noted in Ireland, has lately been under the care of Dr. Joseph Redmond in the Mater Misericordiæ Hospital in Dublin.

Clinical Reports.

A WARD CLINIC IN THE MONTREAL GENERAL HOSPITAL.

By R. L. MacDonnell, M. D.,
Professor of Clinical Medicine in McGill University.

(*Reported by Nurse Alice Hall.*)

Question. Mr. R.,* what cases were under consideration at the last clinic?

Answer. A case of gall-stone colic and a case of chronic pulmonary tuberculosis.

Q. What was the history of the first case?

A. The patient, a man of fifty, was at work laying down pavement a week ago, when he suddenly felt intense pain in the abdomen, he became collapsed, and was sent to the hospital directly. On admission, the pulse was slow, the temperature subnormal, the abdomen tense. Pain and tenderness were extreme but worse in the right hypochondrium.

Q. What did we say were the common causes of sudden, severe abdominal pain in a man of fifty, who had left his home in good health and after two hours became seized as this patient was?

A. Renal or biliary colic; stoppage of the bowels from hernia or some less common cause; sudden peritonitis from perforation of an ulcer, especially in the neighborhood of the appendix; and ordinary intestinal colic.

Q. What cause was diagnosticated in this case?

A. Gall-stone colic.

Q. Why?

A. There was no evidence of hernia. There was no general peritonitis, for the abdominal pain very soon became confined to the right hypochondriac region. The pain resembled that experienced in gall-stone colic, being paroxysmal and very severe. There was no intestinal stoppage, for the patient passed both flatus and fæces during the first twenty-four hours he was in the hospital.

Q. Can you exclude renal colic?

A. No.

Q. Were there any further evidences of gall stone?

A. After forty-eight hours there was slight yellowness of the conjunctiva, and bile was found in the urine.

Q. Was there any jaundice of the skin?

A. None was evident.

Q. Therefore you think you have evidence of gall-stone colic?

A. Not complete evidence, for the stone was not found.

Q. The nurse says that, though the stools have been most carefully examined and strained, yet no stone has been found. What may have occurred?

A. The stone may have slipped back or it may have been arrested in the duct, allowing the bile to pass it, which may account for the absence of jaundice.

Q. Then in what respects did this man Duffield's attack differ from renal colic?

A. In the character of the pain and its locality; and in the fact that it was unaccompanied by frequency of micturition or by shooting pains into the groin.

Q. How was he treated?

* At McGill University two complete years of study are devoted to clinical work. Professor MacDonnell's class is composed only of those who have spent three years already in medical study and who will be candidates for the degree in March, 1891.

A. On admission a hypodermic injection of morphine (gr. ¼) was given, and several times repeated. He was also given small doses of calomel.

Q. And the result?

A. The symptoms are entirely relieved.

Q. Do you remember the condition of his liver?

A. The liver was enlarged, extending two inches below the margin of the ribs, and measuring six inches in the right mammary line.

Q. How was this accounted for?

A. You said it was possible that this might be the result of an early stage of cirrhosis of the liver.

Q. What right had I to assume such a thing?

A. Because the patient owned up to having been all his life most intemperate, especially in the matter of gin, and you pointed out the stellate veins upon his nose.

Q. Were there any other evidences of cirrhosis of the liver?*

A. No.

Q. Mr. C. D., what were the physical signs present in the second case we examined?

A. Diminished expansion of the right side of the chest; dullness on percussion of the left apex as far down as the third rib; and dullness at the right apex, extending to a lower level, but with a less defined lower margin and a corresponding area of dullness posteriorly.

Q. And with the stethoscope?

A. The breath sounds were harsh and subcrepitant râles were audible, especially at the right apex.

Q. What important aid to diagnosis was unmentioned?

A. Examination of the sputum.

Q. Mr. Farwell, you are the clinical clerk in charge of this case; what report have you to make?

A. (*Mr. Farwell.*) I have examined the sputa in the pathological laboratory. The mass brought up in the morning is muco-purulent and nummular, and contains elastic tissue, also a few tubercle bacilli in every slide examined.

Q. Mr. C. D., of what use is this report?

A. It is positive evidence of the nature of the disease.

Q. Were any important symptoms of pulmonary tuberculosis absent?

A. Hæmoptysis, night-sweats, and fever.

Q. What symptoms were present?

A. Cough, debility, loss of weight.

Case I.—*Dr. MacDonnell:* The new case I present to you to-day is that of John Farrell, aged sixty-six, a laborer, who was admitted on the 24th of October—*i. e.*, thirteen days ago. He was sent in from the out-patient room because he had sciatica. He complained of pain down the back of the left thigh, which was very severe and kept him from earning his living. There were also pains in the shoulders and arms, but there was no stiffness of the joints. He owns to having been very intemperate, but he says that he has never had rheumatism.

The family history—which is given in detail in the report I have here furnished by Mr. Morrow, the clinical clerk in charge—is negative.

After his admission we found physical signs of an emphysematous condition of his lungs, and some of you will remember that I pointed this out as being not uncommonly found in old people. The area of cardiac dullness was not encroached upon, but it was increased in extent, the apex beating under the nipple, and I said that probably the heart was much larger than the area of dullness represented, owing to the emphysema of the lungs. The sounds were somewhat weak, but there were no murmurs. There were no evidences of disease elsewhere. The pains were disappearing gradually, and the general condition was improving, when, upon the night of the 30th of October, a certain change took place, of which the patient will tell us himself. What happened to you on the night of the 30th of October?

The Patient: I went to bed as well as ever I was, with the exception of the old pains in my leg. About eleven o'clock I was seized with a violent pain, which ran from the pit of my stomach up to my neck. I could not get any breath on account of the pain, and I thought I was going to die. I was in a fearful state with shortness of breath. The nurse saw I was bad and sent for the house doctor.

Q. What did he do?

A. He ordered hot poultices and put something sharp into my arm, and after that I felt better.

Q. Did you have any chill? Did your teeth chatter, and did you feel cold?

A. No, sir.

Q. Did you have any sharp pain in either side of your chest?

A. No, sir. It was just in the middle and ran from there to there (from the top of the sternum to the epigastrium).

Q. Mr. E. F., here is an old man who, apparently in good health, for his sciatica was nearly well, goes to bed and awakes in urgent pain and dyspnœa. Can you suggest a cause?

A. It might be pneumonia.

Q. Why pneumonia?

A. Because pneumonia is sudden in old people.

Q. Would your stethoscope help you?

A. It might not, because the physical signs may not be present.

Q. What else might it be?

A. Angina from old heart affection.

Q. What else?

A. Acute pleurisy.

Q. One serous membrane can be affected, so can another?

A. Yes. It might be acute pericarditis.

Q. What symptoms of a sudden pneumonia are absent?

A. Chill and pain in the side.

Dr. MacDonnell: The report of the night nurse and that of the house physician corroborate that of the patient, which he has given remarkably clearly. Dr. McKechnie found no cause for the pain until the following day, when a very loud friction murmur became evident. I heard it on the morning of the 1st of November, and I have never heard any pericardiac friction sound so loud and distinct. There was no evidence of fluid in the pericardium. The friction sound was limited to an area of about the size of a half dollar, situated just where the fourth rib meets the sternum on the right side. It accompanied both sounds of the heart and was unaffected by a cessation of breathing.

On the night of the attack he went to bed with a normal temperature, but by the following morning it had risen two degrees and remained high until two days ago. The pulse ran up from 66 to 104. The respirations were not at all increased in number. (A point against the diagnosis of pneumonia.)

Q. Examine the chest thoroughly. What is the condition of the lungs? Are there any evidences of pleurisy or pneumonia?

A. No.

* The temperature rose from 97° on the morning of admission steadily to 100° on the following morning. On the fourth evening it was 102·5°, on the fifth 101·5°, and did not come to normal until the end of the first week, when it suddenly fell, coincidently with the disappearance of the abdominal pain.

Q. Now put your stethoscope just here (at the junction of the fourth right costal cartilage and the sternum) and make slight pressure with it. What do you hear?

A. A friction sound.

Q. With what sounds is it synchronous?

A. With the heart sounds. It accompanies both.

Q. Have you found a cause for the illness of the 30th of October?

A. Yes. He probably had acute pericarditis.

Q. Can you positively exclude pneumonia? Remember that pneumonia and pericarditis often go together in the same subject.

A. The subsequent history is not that of pneumonia.

Q. Are you satisfied that he has acute pericarditis and that the onset of this disease was the cause of this attack on the night of the 30th of October?

A. Yes.

Q. Do you think it probable that acute pericarditis could occur without a cause, and until to-day we can not find one? Remember he has been ill for three days. What is the most common cause of pericarditis?

A. Rheumatism.

Dr. MacDonnell: The other causes are traumatism, which we need not consider; infectious diseases, which he has not; and Bright's disease, which we can exclude by the examination of the urine. The cause became apparent yesterday morning, when he began to complain of pain in the left great toe joint and afterward of pain in the right toe joint. Although he denies ever having had rheumatism, yet he acknowledges an old friend in this swelling of his left foot. He says he had an attack just like this in his left foot seven years ago. It never touched any other joint.

There is evidently now an acute joint affection to accompany the pericarditis, and that joint affection looks to me very much like gout. Acute rheumatism does not usually attack people for the first time at the age of fifty-nine; on the contrary, it is very rare for it to attack after thirty. And this old man, whom we have no reason for disbelieving, declares that he never had any joint affection in his life except this one attack in the left toe joint seven years ago.

1. Age is one point against acute rheumatism.

2. The joint affected is gout's own joint. It has attacked both of them.* Rheumatism prefers the medium joints, like the elbow and wrist.

3. The character of the swelling resembles that of gout. The tissues are red and glazed all round the joint. It looks hot and angry, and you can perceive it is exquisitely painful.

The points against the diagnosis of acute gout are these:

1. The absence of previous attacks save the one mentioned.

2. The presence of pericarditis, which is so common a complication of rheumatism and which is so rarely mentioned in connection with gout.

3. The rapid relief which followed the administration of the salicylates.

Altogether it is most probable that we are dealing with acute rheumatism, modified by the age of the patient and by a previous attack, as well as by the fact that he met with his illness in hospital where appropriate treatment was immediately at hand.†

Dr. MacDonnell: This patient, whom I present to you for the first time to-day, is John Jough, aged seventy-seven, formerly a sailor in the Royal Navy, latterly a journeyman tailor. He was admitted on the 30th of October, 1890. He says that he enjoyed good health until about four years ago, when his sight began to fail him and he could no longer work at his trade. For about the same period he has suffered from cough, pains in the chest, and breathlessness upon exertion. On the 30th—that is, four days ago—he went to get some medicine at the out-patient department of the hospital, and on the way home was seized with severe pain in the right side, shivering, and a sense of very great weakness, so that he could no longer walk, but was obliged to lie down on the pavement. The ambulance was summoned and he was brought to the hospital.

Q. Mr. F. G., can you suggest a cause for chill, pain in the side, and sudden prostration in a feeble old man?

A. It might be pneumonia.

Dr. MacDonnell: He was accordingly given a bed in this ward, and the following state on admission is noted in the report handed to me now by Mr. Dewar, the clinical clerk: The patient presented an anxious appearance and was evidently short of breath. There was a very distinct malar blush. He complained of weakness and pain at the pit of the stomach. The temperature was 100°; pulse 86; respiration 36. There was no cough.

Q. What physical signs are present?

A. The left side of the chest expands better than the right.

Q. Can you find the apex beat of the heart?

A. It is here, a good inch outside the nipple line.

Q. What other signs are there?

A. The area of superficial dullness of the heart is increased. It begins above at the third rib in the middle line; laterally, it extends from the right border of the sternum to the apex beat, just one inch outside the nipple line.

Q. Now listen to the heart sounds. What do you hear?

A. A very loud systolic murmur at the apex and a double murmur at the aortic cartilage.*

Q. Now percuss the lungs.

A. Both lungs are clear in front on percussion. Behind, the left lung is quite clear to the base, but the right lung is dull from the angle of the scapula to the base.

Q. The stethoscopic signs?

A. Bronchial breathing is very well marked over the dull area at the right pulmonary base. The respiration is hurried. There are mucous râles on inspiration and expiration. The vocal resonance is increased.

Q. Now the liver and spleen?

A. No signs of enlargement.

Q. The urine is reported to afford negative evidence of disease; what is your diagnosis?

A. Acute pneumonia with heart disease.

Q. What is the nature of the heart disease?

A. Valvular disease with hypertrophy.

Q. Of old standing?

A. Yes.

Q. Why?

A. Because there is evident enlargement of the heart.

Q. How does that tally with the history?

A. He said that he had cough, dyspnœa, and pain in the chest for several years.

Dr. MacDonnell: There are many instructive points in connection with this case. The diagnosis is plain. First, most probably as a result of atheromatous change, the valves have become incompetent; an hypertrophy of the walls of the heart has occurred which has completely compensated for the valvu-

* The joints subsequently involved were the metacarpo-phalangeal joint of the right hand and the metatarso-phalangeal joints of both feet.

† *November 14, 1890.*—No appreciable effusion into the pericardium has taken place. The joint affection has quite subsided.

* Capillary pulse was well marked in the finger-nails during the period of pyrexia, but after the temperature became normal it was lost.

lar defect, as is evidenced by the fact that he has never had dropsy of the feet, but probably compensation is beginning to fail and he applies for relief at the out patient room. Probably the exertion of getting home brought about a condition of pulmonary stasis which may have predisposed to pneumonia, or the lungs may habitually have been in an engorged condition, ready to take on that disease. When an old person is attacked with severe pain in the side and chill, the diagnosis of pneumonia is almost certain. The malar flush in an old person is very suggestive, and here it was coupled with hurried breathing and fever. Even in the absence of physical signs the diagnosis would be almost complete.

Two important symptoms of pneumonia were absent—cough and rusty expectoration. Both these symptoms are often absent in pneumonia, and are generally absent in senile pneumonia.

Q. (*To patient*). How is your cough since you came in?

A. Better.

Q. Do you cough at all?

A. Scarcely at all.

Q. Did you cough much before you came in?

A. Yes, a great deal.

Dr. MacDonnell: It would appear as if his acute pneumonia had cured his cough, and this has often been noticed. Patients who have chronic bronchitis with winter cough and who contract pneumonia are often relieved of their cough while the pneumonia is in progress.

Q. Are you short of breath now?

A. No, sir.

Q. Were you short before you came in—more than you are now?

A. Yes.

Dr. MacDonnell: The same is true of dyspnœa. Persons habitually short-winded do not appear to be so breathless when pneumonia attacks them as those whom the disease strikes when in good health.

(*The patient's bed is removed.*) In senile pneumonia the patient may die before physical signs have time to develop. Our pathological friends very often find pneumonias of whose existence we were not aware. Pneumonia is a very common cause of death in elderly people, and is frequently overlooked.

The physical signs differ from those of ordinary pneumonia. The dullness may not be perceptible. The crepitant râle is nearly always entirely absent and is replaced by the mucous râle such as we have heard here. But the breathing readily takes on a blowing character.

As to the prognosis of this case—when I examined the patient the day before yesterday I told my house physician that I thought the old man would die. He was very feeble; he already had advanced cardiac disease which would be likely to impede the action of the lungs, which were now seriously attacked. But to-day he seems better. There is improvement in every symptom and the disease does not appear to have spread. This is the fifth day, and we may expect a crisis before many more.

The treatment in these cases is not one of drugs. A patient in this condition must have the most nourishing diet and a free supply of stimulants. I ordered him twelve ounces of whisky in the twenty-four hours and no medicine.*

The New York Polyclinic.—Dr. James P. Tuttle has been appointed lecturer on diseases of the rectum and anus, and announces that he will hold clinics on Tuesdays and Fridays, at 7 P. M.

* The patient eventually made a good recovery.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. APPLETON & CO.

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 27, 1890.

LABORATORY RESEARCHES REGARDING EPHEMERAL FEVERS.

THE causation of febriculæ has been the subject of some original experiments by Roussy, whose contributions have recently been published in the *Archives de physiologie*. His paper is a significant addition to our knowledge of the febrile process in certain minor affections that have hitherto received very little attention at the hands of biologists. He has observed, in the first place, the frequent occurrence of cases of high temperature of short duration, the cause of which has been the ingestion of stale beer, decayed fish, or stagnant water containing vegetable matter, such as hay, leaves, etc. The author holds the opinion that the cause of this kind of pyrexia is not a specific micro-organism, but a soluble chemical substance. Animals were experimented upon by intravenous injections of water containing decaying organic substances, with the result of producing intense fever, the temperature going as high as 107·5° F., with decided symptoms of gastro-intestinal disturbance. A like quantity of the same fluid taken into the stomach produced neither febrile nor digestive derangement.

Roussy paid particular attention to the high fever caused by the yeast of beer. That substance, when rubbed up with distilled water and after twenty-four hours filtered, yielded a filtrate which, injected under the skin, was followed by sharp pyrexia lasting from twelve to fifteen hours. That this fever was not due to the mechanical or other effects of the contained germs was proved by the fact that when a quantity of the yeast cells was collected on a filter and dried at 270° F., and then prepared for subcutaneous injection in distilled water, no pyrexial action was observed. That the fever was caused by the product of the living cell was shown by cultivating the yeast in bouillon and then carefully washing the cells at the bottom of the glass with sterilized water and allowing them to stand for three days. The injection of this material was followed by the same febrile agitation as that already observed to be due to the stale-beer injections. By a somewhat laborious process, Roussy was able to isolate a granular mass of a light-yellow color which caused febrile action when injected. This mass deliquesced upon exposure, forming a syrupy substance that adhered tenaciously to the sides of the vessel when dried. In a desiccator the precipitate became white and slightly scaly, and was readily pulverized; placed upon the tongue, it rapidly melted, at first giving a resinous taste, and after that a biting sensation which rose to a sense of strangulation. To this substance the author has given the name of pyretogenin. Small subcutaneous injections of this

fever-producer caused in animals a rise of temperature within an hour or half-hour, often as bigh as 107° F., and accompanied by chills, vomiting, and diarrhœa. The pulse was frequent, hard, and small, and the skin was dry. There was an increase, during the febrile movement, in the amount of urea and carbonic acid eliminated. After six or seven hours the animal was again in a normal condition.

MINOR PARAGRAPHS.

DIABETIC PARAPLEGIA.

The *London Medical Record* quotes from a recent lecture by Charcot on the organic or dynamic affections of the lower limbs, in the course of which the subject of diabetic paraplegia was considered. Since 1880, when Jules Worms wrote of the symmetrical neuralgias of diabetic patients, other writers, such as von Ziemssen, Buzzard, and Bernard, have pointed out other neuropathic conditions, such as formication, hyperæsthesia, dysæsthesiæ, and even absence of the knee-jerk, as the result of diabetes. The absence of the knee-jerk, in cases that are grave but not of necessity grave because of the large quantity of sugar excreted, is apparently the result of a peripheral neuritis, the spinal cord being found intact. In some cases locomotor ataxia is simulated by this symptom, by the lightning pains, by other sensory disturbances, and by the ataxic gait. But neither in the diabetic ataxia nor in the alcoholic variety is the gait really that of tabes, the muscular paralysis being most marked in the extensors of the foot. In fact, in all the forms of pseudo-tabes, whether diabetic, alcoholic, saturnine, arsenical, or from beri-beri, we see the "steppage," not the true ataxic walk. The front part of the foot falls, and the patient is obliged to step higher than usual to prevent the toes from catching the ground. The paralyzed muscles show the electrical reaction of degeneration. The spinal cord, however, is not the site of serious alteration, the posterior columns especially remaining quite free from impairment. In diabetic paraplegia there is not that pain on pressure of the limb found in the alcoholic variety, but the feet fall even when the patient is seated. Taken as a whole, the case exhibited by the lecturer bore the closest resemblance to the alcoholic cases, but there was no alcoholism about it.

THE NEW SURGEON-GENERAL OF THE ARMY.

Among the nominations sent to the Senate, by the President, on the 23d inst., was that of Dr. Charles Sutherland, to be Surgeon-General of the army. Dr. Sutherland entered the medical department of the army in 1852 and is, to-day, the ranking Colonel in that department. His services during the war of the rebellion won for him the brevets of Lieutenant-Colonel and Colonel; and his appointment to the highest position in the department is but a just recognition of those services. In 1866 he was appointed Assistant Medical Purveyor, and his experience in that capacity fits him for the office which, we feel assured, he will fill with credit to himself and to the corps which he represents.

THE LIBRARY OF THE NEW YORK HOSPITAL.

On the 1st of January the librarian, Dr. John L. Vandervoort, will retire from the office of which he has discharged the duties almost continuously since 1837. At the time of his appointment the library consisted of only 4,166 volumes, and was open for the delivery of books to those privileged to use them only on stated days, and for from an hour and a half to two hours at a time. It was not for some years after that that a daily service was established. From the time of the dismantling of the old hospital building in Broadway to the opening of the present building in Fifteenth Street, the library was moved several times, but during all that time Dr. Vandervoort managed to make it available to those who had occasion to make use of it. It is soon to be moved into a new building adjacent to its present quarters. More than 14,000 volumes have been added to it during Dr. Vandervoort's tenure of office. We learn that his son will continue to discharge the duties of assistant librarian. Both the hospital authorities and the medical profession of New York are indebted to Dr. Vandervoort for his long and intelligent service.

A CHRISTMAS SENTIMENT REGARDING THE MEDICAL PROFESSION.

The following seasonable tribute to our profession may be found in the Christmas number of *All the Year Round* in a story by Fargeon: "Surely there must be some beneficent influence at work that humanizes and softens the heart, that makes it respond willingly and cheerfully to the appeals of those who suffer! Numberless are the instances that can be adduced of the wonderful goodness of physicians, renowned and eminent, who sacrifice their time without expectation or desire of return for the inestimable services they render. I have no hesitation in saying that of all arts it is the most ennobling and beautiful, and that its record of kind deeds is matchless and unapproachable. With all my heart I say, 'Heaven bless the doctors for all the good they do, for the good they are enabled to do.'"

A CONTRIBUTION TO THE ÆTIOLGY OF JACKSONIAN EPILEPSY.

In the *Archiv für pathologische Anatomie und Physiologie und für klinische Medicin*, Dr. K. Yamagiwa calls attention to two cases of severe cortical epilepsy in which post-mortem sections of the brain revealed disseminated patches of *Distoma pulmonale* in the cortex. Microecopic examination showed, in connection with the parasites, giant-cell and round-cell infiltration, thickened blood-vessel walls, and new connective-tissue growth. Further research disclosed the Distoma in the lungs.

HEMIANOPSIA FOLLOWING UTERINE HÆMORRHAGE.

Dr. A. Chevallereau, in the October number of the *Archives de tocologie*, details the histories of two cases of hemianopsia which came on after severe uterine hæmorrhage. The author was of the opinion that the prolonged syncope which followed the hæmorrhage might have given rise to blood coagula in some of the branches of the cerebral arteries which supplied that part of the cortex governing vision, or some of the fibers of the optic tract.

THE TETANUS GERM.

Dr. M. Reynier, in the *Revue de chirurgie*, gives the result of various experiments on animals with a culture of tetanus germs. In every instance, after the inoculation the typical symptoms were developed, and death followed in a short time. The microscope demonstrated the bacilli of Nicolaier in every case.

THE CORROSIVE-SUBLIMATE TREATMENT OF GRANULAR CONJUNCTIVITIS.

The treatment of different forms of granular conjunctivitis with various strengths of corrosive-sublimate solution seems to have given good results in the hands of Guaita (*Annales d'oculistique*). The details of the treatment are published in the *Union médicale*. The sublimate is used in strengths of from 1 to 300 to 1 to 500, and it is applied to the palpebral conjunctiva with a camel's-hair brush every two hours or according to the severity of the case. If the disease is slight, a collyrium of 1 to 1,000 is given. There have been no symptoms of poisoning or complications to the cornea from this method, but very prompt amelioration of the symptoms has followed its employment in every instance.

AN EPIDEMIC OF TUBERCULAR PNEUMONIA.

Dr. Küssner, in the *Centralblatt für klinische Medicin*, mentions five cases of this affection, the histories of which had been previously published by Dr. L. Dor, in the *Province médicale*. The cases had occurred in close connection in a hospital ward. Four of them were rapidly fatal; the fifth ended in recovery. Autopsies disclosed the fact that tubercle bacilli were present, though no marked symptom had existed during life. There was great infiltration of the lung tissue, and, besides the characteristic bacilli, there was another micro-organism present, the one which had evidently caused the rapid course of the pneumonia.

ITEMS, ETC.

The Koch Treatment at the County Medical Society.—On Monday evening, the 22d inst., a very large audience of physicians assembled at the monthly meeting of the Medical Society of the County of New York to listen to the first public report made in New York on the subject of Koch's treatment of tuberculous disease as observed by Dr. John H. Linsley in Berlin. The speaker, who had followed the treatment in Gerhardt's clinic at the Charité, prefaced his statements by an effective word picture of the daily scenes at the opening of each clinic. He described the halls and approaches to the clinic rooms as so thronged by physicians as to be almost impassable to the patients as they elbowed their way to the professor's table, each with a glass containing the individual's sputum. If examination demonstrated the presence of tubercle bacilli, each patient received as a first injection one milligramme of the liquid. The patients were then put to bed and the changes in their condition were carefully noted. No previous histories of the cases were taken, and no effort was made to obtain them. The inoculating needle was used from one patient to another, and no attempt was made at cleansing or disinfecting it. No local irritation at the site of the puncture had followed in any of the cases observed. The only precaution taken was the immersion of the needle and syringe in absolute alcohol before this general use. The characteristic results usually made their appearance in from two to thirty hours after the inoculation. The first symptom of reaction was the rise of temperature, which varied from 100° to 106° F., though occasionally it became subnormal. This was followed by persistent headache, pain in the back and limbs, and usually a sharp chill. These disturbances generally subsided within twenty-four hours. The second injection was not given until all symptoms of the initial reaction had entirely disappeared, and all subsequent injections were administered upon this basis. The dose in pulmonary cases was gradually increased to ten milligrammes. The patients were examined as to their general condition every two hours.

The reactions were of so varied a character that the speaker thought the treatment should only be carried on, at least at present, in a properly officered institution. Gerhardt had not discharged as cured any of his patients with phthisis pulmonalis. He had stated that the sputum in this class of cases was at first increased in quantity and became thicker, and then got thinner and mucoid in character. The number of bacilli was often found to be increased, but they gradually seemed to undergo a certain involution process; they would become club-shaped and appeared to be suffering from an insufficient or improper pabulum. The weight of many of the patients increased and there was a cessation of night sweats, with apparent improvement in the general health. Professor Gerhardt had stated that the effects in these cases of phthisis could not be demonstrated for many months. He had expressed himself as considering the prospects most encouraging. Dr. Linsley then detailed what he had seen of the lupus cases in the clinic, and his statements agreed with those made by Dr. Stearns, whose observations are recorded in full in this issue. While, he said, there was little doubt that ere long the liquid would be made on a large scale by the German Government, still it was hinted that there existed at present points of detail on which Koch and the Government were not quite in accord. It was very doubtful, in the speaker's opinion, if the actual composition of the liquid would be made known for a long time. It had been suggested by the German physicians that Koch was not quite satisfied with the therapeutical effects so far achieved, and that, if by further work he could find some other ingredient to add to its efficacy, it would be to his interest to do so, and until then he should abstain from any direct statements as to the composition.

Dr. F. Warner, who had on that day returned from Berlin, where he said he had had ample opportunity to make the injections and to watch the results, substantiated Dr. Linsley's remarks in general terms. Of the pulmonary cases, he stated that he had not observed any results worth recording, though it must be admitted that many of the cases treated had been in very advanced stages. He had seen some very good results in cases of laryngeal tuberculosis.

Dr. S. Baruch said that he had made, so far, sixty-six injections on thirteen patients. The injections had been given by his house physician, Dr. Max Rosenthal, at the Montefiore Home. While it was too soon to hazard any conclusions, he might say that, as a general proposition, the cough and expectoration had decreased in the pulmonary cases. Two of the Home patients who were about to be discharged as cured of pre-existing pulmonary lesions had been given an injection of one milligramme, under which they had undergone immediate reaction. He thought these experiments confirmed very prettily the allegations made as to the diagnostic value of the injections.

The University Medical Magazine.—It is announced that the size of this excellent journal is soon to be increased by the addition of from sixteen to twenty-four pages to each number, mainly to give space for fuller abstracts of current literature under the direction of Dr. William Pepper and Dr. James Tyson (medicine), Dr. D. Hayes Agnew and Dr. J. William White (surgery), Dr. Horatio C. Wood (therapeutics), Dr. William Goodell (gynæcology), and Dr. Barton C. Hirst (obstetrics).

The Brooklyn Post-graduate Undertaking.—Articles of incorporation have been filed in Brooklyn as a first step toward the establishment of a post-graduate hospital and school in that city. The management of the institution will be vested in a board of medical councilors, among whom are Dr. Charles Jewett, Dr. Fowler, Dr. Jeffrey, Dr. Evans, and Dr. Butler. The aim of the faculty will be to cover every field of study in surgery and practical medicine. An outdoor department is included in the future scope of the enterprise.

Society Meetings for the Coming Week:

Tuesday, *December 30th:* Boston Society of Medical Sciences (private).

Wednesday, *December 31st:* Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield).

Thursday, *January 1st:* New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Washington, Vt., County Medical Society (annual—Montpelier).

Friday, *January 2d:* Practitioners' Society of New York (private) Baltimore Clinical Society.

Saturday, *January 3d:* Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Letters to the Editor.

ALVEOLAR ABSCESS; A REJOINDER TO DR. M. L. RHEIN.

New York, *December 15, 1890.*

To the Editor of the New York Medical Journal:

Sir: In your issue for December 6th a letter appears, written by Dr. M. L. Rhein, criticising my article, The Importance of Prompt Treatment in Alveolar Abscess, published in your Journal for November 22d. I should like to reply to the same.

I am aware that oral and dental surgery have been recognized as specialties in medicine, but I am also aware that large numbers of patients suffering from alveolar abscess present themselves every year in all the large hospitals and dispensaries and to the general surgeon for relief, and that they require "prompt treatment."

The ætiology of the fistulæ resulting from these cases has sometimes puzzled the ablest surgeons, so it is not strange that patients should consult their physicians about them and not the dentist.

I regret that I can not accept the compliment the writer pays me when he calls the classification of these abscesses which I have chosen—viz., into superficial and deep—"original" with me.

He will find the same division given in an article by Dr. Briggs, entitled Diseases and Injuries of the Jaws, in the *Reference Hand-book of the Medical Sciences.*

This division seems a most natural one, and the dividing line to be the fold of mucous membrane passing from the cheek to the gum. In the superficial form the apex of tooth-root does not pass below this fold; in the deep form it does.

This is a point made by both Bryant and Holmes in their *Systems of Surgery.*

As these abscesses have a tendency to point in a direction horizontal to the point of origin, the former usually burst into the mouth and the latter (when on the outer alveolar surface) externally upon the face. Of course, either of these may be acute or chronic. To call one abscess chronic simply because it opens into the mouth and another acute because it penetrates the deeper tissues and burrows in all directions seems absurd. The first attack of the superficial form is certainly an acute affair, and when abscesses of the deep form burst externally they are generally chronic enough to suit the most fastidious. The writer's "embarrassment" over the lack of information of the profession on dental topics is truly touching, but I have yet to know that a fair knowledge of dental pathology in its relation to diseases of the jaw is not of far more importance to the surgeon than the anatomy of the lower extremities is to the student of dentistry.

Speaking of the pathology of these cases, I remarked that the "products of decomposition pass through the tooth canal and set up an acute inflammation of the circumdental membrane," and the word periosteum was not used, as the writer hints.

He hopes to instruct the profession by use of the word pericementum, but, according to the *American System of Dentistry*, vol. iii, page 660, pericementum, peridental membrane, dental periosteum, etc., are synonyms.

We are further informed that this inflammation is due to a putrefaction of the dead pulp. Dr. Rhein might have gone a step further and spoken of the micro organisms which cause this.

Although a tooth may be fairly well nourished by its circumdental membrane, when the pulp of a tooth is dead, producing the characteristic discoloration, when there is insensibility to heat and cold and the tendency to periodontitis, the tooth is generally designated as dead.

In speaking of the treatment of these cases hardly anything was said about the superficial form, or "gum-boil." Its course is usually short, and rupture into the mouth occurs either spontaneously or from slight pressure. The patient consults his dentist about these matters; they are of little or no interest to the physician. It is "the dangerous and insidious cases" in which there is "great danger . . . from septic symptoms . . . due to the absorption of pus" (as the writer remarks) that concern the physician.

The writer's desire to save the tooth is a laudable one, and the method of treatment he prescribes should have been mentioned in my article when speaking of abortive measures. That more particularly concerns the dentist, however.

If the cases could be seen in time, I have no doubt many teeth might be saved; but there lies the difficulty. Frequently these patients consult no one until suppuration has taken place, considerable of the alveolar process has been absorbed, and the surrounding tissues are infiltrated.

In such a case I doubt if any injections of hydrogen peroxide or bichloride of mercury are alone enough to stop the process. Moreover, many of these abscesses are due to the stump of a root wholly or in part covered up by the gum.

I infer from Dr. Rhein's letter that, even after the most careful treatment, the trouble may recur, and I believe this is the case much oftener than he is willing to admit. I have seen several patients lately in private practice who had had this very experience, and, after weeks of treatment, finally became disgusted and had the teeth drawn, when the trouble ceased at once. I have had a little personal experience also in this matter which I am not likely to forget. Following the treatment of a tooth in a similar condition, after the manner described by him, I had a number of mild attacks of alveolar abscess which were aborted, but in January last one came on which could not be cut short. In an almost incredibly short time the face became frightfully swollen and the temperature rose to 103° F.

A professional friend was called, who, after other means had failed, ordered the tooth extracted. A free incision was made within the mouth, when quite extensive periostitis of the jaw was found. Two weeks and a half of careful treatment were required before it was healed up.

It is hardly necessary to say, I wish the tooth had been drawn some time before. My critic remarks that he has never known extraction to be delayed when it has been "determined upon." There is just the point; when is it determined upon?

Desire to save a useful organ may cause delayed extraction, but not infrequently, I am afraid, there is another reason.

There seems to be (with many) a dread of some impending danger if the tooth is drawn while the inflammatory process is at its height.

In an article by Heath, in his *Diseases and Injuries of the Jaws*, Mr. Cattlin, F. R. C. S. (who was then president of a dental association in England), is quoted as follows: "It was the erring practice of some to wait until the inflammation had subsided; but if the tooth be retained . . . sometimes causes necrosis . . . often ending in abscess . . . permanently disfigures the face."

This is no "misconception of facts," but frequently when such a patient is directed to a dentist by his physician, a message must be sent by the latter saying that he will take the responsibility of extraction. This is a fact well known to physicians, and since the publication of the article in question I have had letters from several members of the profession saying this had been their experience also.

Trouble may follow, it is true, in rare instances, as after any

other surgical procedure, even the most trivial. The remark of the doctor about extraction being only useful in dispensary practice would seem to imply that these teeth are only retained in the wealthy, who can afford to pay for weeks of treatment (even if the tooth has to come out in the end).

The writer's comparison of false teeth to artificial eyes shows a lack of appreciation for that marvelous and beautiful organ which is so well called "the light of the soul." The artificial eye, no matter what material it may be made from, never attempts to replace the function of the natural organ, but is only for appearance, whereas I know of several instances in which troublesome teeth have had much to do with the patients' ill-health, and in which, after they were extracted and replaced by artificial ones, the digestion and general health rapidly improved. Surely in these cases the artificial teeth were better than the natural ones.

In reference to the treatment of these abscesses by extraction, I will quote a few authors: Holmes, *System of Surgery*, says: "In all cases of alveolar abscess, extraction of the diseased or dead tooth is the cure." Tomes, *Dental Surgery*, says: "If inflammatory action has gone on for a day or two, it is probable that suppuration can not be avoided, . . . in that case the tooth should be removed."

Heath, *Diseases and Injuries of the Jaws*, says: "If there be an obvious source of local irritation, extraction of the tooth, or stump of a tooth, should be immediately performed." Bryant, *System of Surgery*, says: "In alveolar abscess of the lower jaw, a prominence passing out from any diseased tooth . . . will point to the tooth which should be extracted."

Garretson, in his *System of Oral Surgery*, 1890, gives many cases in which fistulæ due to alveolar abscess were treated by extraction, and rapid recovery followed.

In the *Reference Hand-book of the Medical Sciences*, article on Diseases and Injuries of the Jaws, Dr. Briggs says: "The treatment of alveolar abscess is free incision and extraction of the peccant tooth."

Many other authors might be quoted if time and space permitted.

However, there are two sides to every question, notably so in medicine, and the treatment of alveolar abscess is no exception to the rule.

Any number of works on dentistry could be referred to, I presume, telling how these abscesses have been treated by injections of carbolic acid, etc.; how the tooth has been extracted, more or less of its root amputated, the alveolar cavity cleansed, and the tooth returned to its socket, where it has reunited; in others, how the roots have been amputated, and more or less of the alveolar process removed with the tooth *in situ*, and many other forms of treatment. But, nevertheless, the fact remains that the shortest, surest, and quickest treatment of alveolar abscess (when the trouble can not be aborted) is early extraction.

J. D. MacPherson, M. D.

Proceedings of Societies.

SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

Third Annual Meeting, held in Atlanta, Georgia, November 11, 12, and 13, 1890.

The President, Dr. George J. Engelmann, of St. Louis, in the Chair.

How shall we treat our Cases of Pelvic Inflammation?—A paper on this subject, by Dr. R. B. Maury, of Memphis, Tenn., gave a comprehensive *résumé* of the pathology of chronic pelvic inflammation as it had been clearly demonstrated by Bernutz, Polk, Coe, and others, and by the results of abdominal section. This pathology was that of pelvic peritonitis dependent upon tubal disease, not cellulitis. The author declared the term chronic cellulitis a misnomer, a pathological condition which existed only in the imagination of the physician, a term which had been productive of pernicious results in practice, and which should no longer be used in connection with non-obstetric pelvic inflammation.

When the pathology rested upon such positive and abundant evidence the question might be asked, Why reopen a discussion upon it now? Because it was evident from our society proceedings and hospital reports that great confusion existed in the medical mind to-day in regard to it. Dr. Byrne's case, discussed in the New York Obstetrical Society during the present year, was taken as an illustration. In speaking of such cases, the great tendency to relapses in chronic pelvic inflammation was illustrated by two cases in which purulent tubes were found five and seven years after attacks of peritonitis and when it was supposed the patients had been entirely restored to health. Upon the subject of treatment, the writer admitted that by non-surgical therapeutic measures large intraperitoneal exudations were often absorbed, and even some tubal and ovarian inflammations entirely disappeared, and recovery seemed complete But this was the exception and by no means the rule. For the radical cure of chronic pelvic inflammation non-surgical treatment failed in a majority of the cases. A great many women suffering to a moderate degree continued to do so in spite of the best-directed non-surgical measures, and perhaps wisely elected not to undergo operation. As a rule, the only radical and permanent relief was afforded by removal of the diseased appendages. The treatment of pus collections, of course, required abdominal section.

The Motive and Method of Pelvic Surgery.—Dr. Joseph Price, of Philadelphia, followed with a paper in which he said that pelvic surgery must be considered apart from abdominal surgery. It was distinct from it in the nature of the lesions dealt with, in the difficulties it presented, and in the complications and embarrassments to routine technique. Nowhere as much as in pelvic surgery did the distinction between the general surgeon and the specialist in pelvic disease stand out clearly. Pelvic adhesions in appendicitis, for instance, Mr. Treves would deal with by the knife. If this was feasible, why not put the knife to ovarian and tubal abscess, to all intestinal fixation by inflammatory processes, and the like? The very suggestion of such method to the mind of the specialist accustomed to deal with all the complexities of pelvic surgery was fraught with evil, and this mere suggestion only made it clear that general surgeons, in so far as they were entirely wedded to the knife in removing disease, fell short of the demonstrated harmfulness of its application in pelvic work.

Relative to electricity, the speaker said that electricians yet talked learnedly of the undetermined place of electricity in the treatment of ovarian cysts, but tar-water and tractors had gone to their long rest. The time must yet come when the allegations made for electricity as a universal panacea must be exploded, and its real, limited, and narrow horizon of usefulness be well defined. The pernicious effect of so-called cures of reported complicated cases, adhesions, inflammations, and the like, by men without training, who looked only at the ampèremeter while they adjusted a clay pad or introduced a galvanic sound, was not to be overestimated. He had repeatedly shown, by exhibited specimens, the fallacy of the pretense of exact diagnosis made by these men, and the arguments were irrefutable. He

believed that the only position assumed by the electricians that had the slightest foundation in fact was that electricity would sometimes control hæmorrhage and relieve pain. That it cured either was not proved.

In dealing with adhesions, the first point to be sought after was to find a crease or crevice into which some progress could be made. In separating intestinal adhesions, they should be broken as far from the bowel as possible. The strings of adhesions might be dealt with according to their size; sometimes it was best to remove them; at others there was no necessity for this. In doubtful cases their removal was the better surgery. Once the adherent mass was removed, the ligature should be applied close to the cornu uteri.

In the treatment of extra-uterine pregnancy his urgent advice was to operate without delay when the symptoms pointed to the disease, with the assurance that delay would only complicate matters and sacrifice the life of the mother.

Suprapubic Cystotomy in a Case of Enlarged Prostate.—Dr. W. H. H. Cobb, of Goldsboro, N. C, read a paper on a case of this affection. The patient, a farmer, married, aged forty-nine years, of a rheumatic diathesis, had dated his troubles back to 1881. While attending to the duties of Register of Deeds, he had carelessly allowed overdistention of his bladder to occur, and had suffered more or less since that time. In 1882 he had had an attack of nephritic colic and had passed a small calculus, similar in size and shape to a grain of wheat. On three different occasions he had passed dark, gritty deposits. In 1883 he had suffered much inconvenience and some pain in urinating. In 1887 he had passed a dark, gristly, bloody substance of about the size of a corn-pea, accompanied by much pain and bloody urine. For the past three years he had suffered much with cystitis in a very aggravated form, with great pain and difficulty in defecation; the urine contained much blood, pus, and mucus. The patient's efforts to relieve his bladder and bowels had been tormenting, and night after night had been spent in walking over his premises, with groanings so severe as to disturb his neighbors. The patient had consulted the author on June 15th last, and, from the history of the case, he had suspected vesical calculus, but had failed, upon examination with the sound, to detect any stone. A digital examination, however, *per rectum* had disclosed the right lobe of the prostate greatly enlarged, rough, indurated, exceedingly tender, and sensitive. After consultation by letter with Dr. Hunter McGuire, he had decided upon suprapubic cystotomy as the only hope of permanent relief, which had been done after the method of Dr. McGuire on June 23d. At the expiration of two months (August 23d) he had found the prostate perfectly normal, with no symptoms of cystitis, and had withdrawn the plug, allowing the fistula to unite, which it did in about ten days. His patient now performed the act of urination and defecation without the slightest trouble, expressed himself as entirely relieved, and was at present following his usual vocation.

Inflammation in and about the Head of the Colon.—Dr. L. S McMurtry, of Louisville, read a paper on this subject. He said the teachings to be found in systematic treatises on surgery and practical medicine upon inflammation and its results in and about the caput coli were not only worthless, but positively misleading. This was true not only as to pathology and treatment, but even as to the anatomy and relations of the cæcum and its appendix. It was well known that inflammatory changes in the vermiform appendix were in almost every case the origin and seat of the inflammatory diseases about the caput coli. Inflammation of the cæcum was very rare, yet the testimony of surgeons and pathologists was abundant that, in a certain proportion of cases, cæcitis, with perforation, occurred without involvement of the appendix. Regnier, in 1886, had operated in a case presenting symptoms of intestinal obstruction with peritonitis, doing an abdominal section. At the autopsy, cæcitis, with perforation, had been discovered. In 1888 the speaker had operated in a case of perforative cæcitis, and sutured two perforations in the cæcum. His patient had recovered, and had been present in the surgical section of the American Medical Association in May of that year.

Fæcal impaction had been mentioned by surgical writers as a cause of inflammation about the head of the colon. Pain over the cæcum, with a fæcal mass perceptible on pressure, often occurred, but rarely, if ever, associated with peritonitis. A few weeks since, the reader had seen a case in conjunction, with Dr. H. H. Grant, of Louisville, in which a localized peritonitis had existed in the right iliac fossa, with a well-defined, firm tumor. Abdominal section had been done, and, instead of ecphyaditis, they had found the disease to be cancer of the caput coli. Irrigation and drainage had rescued the patient from the immediate danger begotten by active peritonitis. The patient was a woman of middle age, and the ingrafted peritonitis had presented the symptoms of an acute condition. Malignant disease of the cæcum had not, so far as the writer was aware, been mentioned by writers upon this subject as a probable condition in the diagnosis of deep-seated inflammations of the right iliac fossa. The decision to operate should be determined more by the grade of the inflammation than by the time it had existed. When a diagnosis had been made, and three days had elapsed without subsidence of pulse and temperature, the operation should be done.

The reader submitted the following conclusions: 1. Inflammation about the caput coli was, as a rule, inflammation of the appendix. 2. A certain proportion of cases would end in spontaneous recovery by resolution. In these, recurrence of the disease was common. 3 In the larger proportion the disease would endanger life, and might at any moment assume a condition practically hopeless. 4. Early operative interference involved less danger than delay, and should be resorted to in all cases in which a high grade of inflammation was persistent. 5. The essentials of the operative technique were brief anæsthesia, quick and thorough work, removal of the appendix, irrigation, and drainage. The lateral incision was preferable to the median.

The Causes of Ill Health in American Girls, and the Importance of Female Hygiene, was the subject of the President's address. He showed that the health of the American girl was threatened and impaired by causes more or less avoidable, as they were due to our methods of life, our methods of training and education; that the physique of this girl, most favorably situated amid auspicious possibilities, was imperfect; her brain overworked, her nerve power exhausted, her functions impaired, and reproduction endangered—all by reason of the susceptibility of her peculiar organization, and the increased impressibility of the sensitive system during the years of development, in which it was subjected to the severest strain. The remedy was attention to woman's peculiar organization and the cyclical waves of her dominant function; or, in other words, harmonious development and occupation of nerve and muscle; diminished brain work and nerve stimulation with increased and co-ordinate physical exercise; increased protection and diminished compression by dress; self-knowledge and individual care during periods of heightened susceptibility. Changes were necessary in custom and fashion, in methods of labor and education. A harmonious co education of mind and body should be approximated, with coincident maintenance of proper hygienic conditions.

Indications for Operation in Ectopic Gestation.—Dr. C. A. L. Reed, of Cincinnati, read a paper with this title. He

started with the assumption that the only proper treatment of ectopic gestation was by laparotomy, or, more properly, cœliotomy. While the profession had become practically unanimous that this was the proper line of treatment, the indications for operation had been less definitely decided upon. This conviction had been forced upon the observer, not only by a study of the literature of the subject, but by encountering patients that had been advised against operation by their attending physicians, until hæmorrhage within the pelvis had threatened a fatality, which was but too frequently realized. The most legitimate excuse for this dilatory practice was to be found in the confusion which had arisen with regard to the supposed uniform causal relationship of ruptured ectopic gestation sacs to pelvic hæmatocele, and the division of the latter into "primary" and "secondary" rupture. These terms were unfortunate, and, as used in this connection, might be entirely arbitrary. Primary rupture was made to mean rupture beneath the peritonæum, instead of *first* rupture, as the etymology of the word would imply, while *secondary* rupture was made to mean rupture within the peritonæum instead of second rupture; whereas an intraperitoneal rupture might be, and frequently was, a primary rupture when spoken of with reference to the sequence of events in ectopic gestation. There would be no serious confusion even here if we were not also taught to leave extraperitoneal hæmatoceles alone to be taken care of by absorption, and if we did not add that, as these hæmatoceles were generally caused by ruptured ectopic-gestation sacs, we were to relegate these cases also to the expectant plan of treatment. This conclusion was without warrant, and was responsible for hundreds of deaths annually from this one cause.

The treatment of ectopic gestation premised the diagnosis of this condition. This was obviously difficult, and in the majority of instances could not be arrived at at all, or, if at all, only presumptively; but in all these cases conditions could be found in the pelvis which, if not conclusive of extra-uterine pregnancy, yet constituted conclusive indications for exploratory operation. The presumption of ectopic pregnancy could be arrived at before rupture chiefly by a history of previous sterility, by a previous amenorrhœa, followed after a few weeks by irregular hæmorrhage, by increased tumefaction at either side of or behind the uterus, and by the existence of a false decidua within the uterus. The latter fact might be safely determined by the judicious use of the Emmet curette forceps. The diagnosis after rupture was essentially the diagnosis of internal hæmorrhage. Time wasted either to determine the cause of that hæmorrhage or to find out if it was primary or secondary was criminal. The thing to do was to operate. The position had been taken that time should be allowed for the patient to rally from the shock. One of the author's own patients had died simply because he had waited twelve hours for reaction—a lesson that had taught him the fallacy of the old teaching, and that had since saved lives at his hands. The best way to overcome shock from internal hæmorrhage was to stimulate the patient by giving ether, stop the drain by ligating the bleeding vessels, and rouse the nervous system by washing out the belly with hot water.

The author's conclusions were: 1. The only proper treatment of ectopic gestation was that by abdominal section. 2. The operation should be done in cases before rupture so soon as the condition could be presumptively diagnosticated. 3. The operation should be done in cases after rupture so soon as the evidences of internal hæmorrhage became apparent. 4. In cases in which the period of viability had already been reached without rupture, pregnancy should be allowed to advance to term before operation, but only under the closest possible vigilance. 5. In all cases the appendages from both sides should be removed, provided the condition of the patient would permit of the extension of the operation.

The Local and General Treatment of Gangrenous Wounds and Diseases.—Dr. Bedford Brown, of Alexandria, Virginia, read a paper thus entitled. Many years ago, previous to the late war, Dr. Brown had determined to institute a series of experiments to ascertain the capability of local and general treatment of all gangrenous wounds and diseases that came under his care either for their prevention or arrest. The object was to find local agents possessing active properties as stimulants of vital action in the affected parts; also as means of disinfecting and deodorizing gangrenous sloughs, of hastening their final separation, and for the establishment of a healthy basis for granulation. In cases coming under his care he had found that the old deodorizers failed to accomplish these objects. He had then employed a solution, almost saturated, of sulphate of zinc and dilute sulphuric acid as a local application, which had seemed to meet all the requirements. The first case in which it had been applied was according to the following formula:

℞ Zinci sulphatis..... ℥j;
Aquæ ..... Oj;
Acidi sulph. dil..... ℥ss. M.

After the free application of hot water at 110° F. the solution had been applied every three hours on bats of raw cotton. In the course of two days the sloughs had separated rapidly, leaving a perfectly clean, healthy basis for granulation. This solution evidently possessed active antiseptic properties. It was an admirable deodorizer, it was clean, and cleansed the parts effectually. In cases of great loss of sensation in the parts, weak circulation, reduction of vital action, and depressed vitality he knew of no agents better calculated to arouse nervous action and stagnant circulation, for, as soon as the living basement structure was exposed, it gave rise to intolerable pain. He had used this solution in all forms of gangrenous wounds and diseases—some limited, others extensive and associated with septicæmia—with benefit.

The Treatment of General Septic Peritonitis.—Dr. W. L. Robinson, of Danville, Va., read a paper on this subject, in which he called attention to those cases which tended, by absence of pain and a seemingly improved condition after chill and fever, to mislead as to the necessity of operating, and instanced two cases of recent date, seen in consultation, in which septic peritonitis and secondary abscess had existed in spite of the seemingly favorable condition of the patient. He said that often there was an utter disproportion between the pathological condition and the amount of pain and tenderness—a condition so often seen in puerperal peritonitis. He stated that traumatic abdominal injuries, ecphyaditis, and pelvic inflammations were the chief causes of septic peritonitis, while, of course, any internal or external influence which produced suppuration might be the indirect cause. He agreed with Dr. G. Frank Lydston, of Chicago, that, in children, falls, blows, etc., were the causes generally of peritonitis, and that, because they were too young to direct attention to the seat of injury, we often diagnosticated the disease too late. The author took the stand that gonorrhœa was a frequent cause of septic peritonitis, and the reason why it did not always produce it was that it did not invariably invade the uterus, and, even when it entered the tubes, the adhesions to the ovary rendered it self-limiting.

Removal of Stones from the Female Bladder through the Urethra, with Cases.—Dr. W. O. Roberts, of Louisville, read a paper on this subject, which was devoted simply to his individual experience. The cases thus treated were six in number; the ages of the patients ranged from fifteen to fifty-six years. Four were married, but two only had borne chil-

dren. The stones were phosphatic in four cases, uric acid in one, and an incrusted foreign body in another. In one case, in a very hysterical patient, the stone had for its nucleus a piece of soft wood. In one, the patient had had a vesico-vaginal fistula, which had been closed by an operation some months prior to the occurrence of the symptoms of stone. In another the bladder had been opened by a surgeon in doing an ovariotomy upon the patient a year before the stone was discovered. In four of the cases the stones were single, in one there were two, and in one nine. In this case the patient had passed at various times a number of small stones—from two to seven at a given micturition. These stones had varied in size from that of a grain of wheat to that of a grain of coffee. In two years she had collected one hundred and eighty-four stones, a number not representing all she had passed. The extraction was done in every case under chloroform, the patient being profoundly anæsthetized. The urethral dilatation was begun with forceps, and completed by means of the fingers, the little finger being first introduced, the ring finger next, and finally the index finger. The fingers were well oiled. In Case I the stone had been found to be almost an inch and a half in diameter. In Case II the stone had been found in the urethra, and had proved to be a piece of soft wood heavily incrusted with urinary salts. In Case III the stone had been spherical, and had had a diameter of about half an inch. In Case IV the stone had been ovoid, its long diameter being an inch, the shorter three quarters of an inch. In Case V there had been nine stones, the smallest measuring circumferentially two inches and two inches and a quarter; weight, eighty-four grains.

Wet Antiseptic Dressings in Injuries of the Hand.—Dr. William Perrin Nicolson, of Atlanta, Georgia, presented a paper with this title.

After dwelling upon the importance of the subject, both from the standpoint of the future earning capacity of the patient and the large amount of financial compensation demanded from corporations, he stated that for seven or eight years past he had looked after the surgery of several railroads and manufacturing establishments, and in that time had been called upon to treat more than three hundred hand injuries, representing all grades of injury from slight contusion to complete destruction of the larger part of the hand. The special point that was urged in the paper was the doctrine formulated by Verneuil—never to use a scalpel in a hand injury. The old teaching that when a finger was crushed you should go far enough behind the injury to secure a sound flap and amputate, was pernicious in the extreme, and had cost thousands of fingers that could have been restored to usefulness. Only such parts as were actually destroyed and pulpified should be removed, and all the tissues to come away could be amputated with the scissors. Projecting pieces of bone could be removed with pliers until reduced to the level of the fleshy parts. In compound fractures the parts should be coaptated as well as possible and the line of separation be determined by Nature and under strict antiseptic dressings. Such a slough was harmless. Another point to which attention was forcibly called was the utilization of blood-clot in filling up ragged injuries, and by its substitution the restoration of lost parts. When a finger was crushed off, the end should be trimmed with scissors and the clot utilized in building up a tissue over the bone. In reference to dressings the author said that he had tried almost all varieties, and had finally obtained the most satisfactory results from keeping the parts constantly bathed in a non poisonous antiseptic solution.

In dealing with these wounds, they were first cleansed as well as possible and then bathed in a sublimate solution. Over all wounds a piece of aseptic rubber tissue or oiled silk was placed, then iodoform and sublimate gauze, and finally over all a covering of rubber tissue, into which, at some convenient point, a small opening was made. The patient was then given a bottle of antiseptic solution, to be carried in his pocket if moving about, and instructed to pour, at frequent intervals, enough into this opening to saturate the dressings. He used almost exclusively listerine, combined with a small amount of carbolic acid, in the proportion of half an ounce of the former and half a drachm of the latter, in a six-ounce mixture. If there was much pain, a small amount of aqueous extract of opium was added. These dressings were not disturbed until the third day, when they were removed under strict antisepsis to preserve the integrity of the blood-clot. The wet dressings were replaced at the end of about a week by the ordinary antiseptic dressings, kept moist by an external covering of rubber tissue. Should sloughing occur, it was kept wet for a longer time with the antiseptic. Under this treatment pain was reduced to the minimum. Suppuration never occurred, and the separation of sloughs was facilitated by the warm moisture.

Uterine Moles and their Treatment.—Dr. J. T. Wilson, of Sherman, Texas, read a paper on this subject.

In the few cases that had come under his observation they had been more troublesome and elicited more anxiety than most writers indicated they should, and the hæmorrhages in some of the cases had been alarming; then, too, there were some points noticed in his cases which he had failed to find described in text-books. All authorities seemed agreed upon the ætiological and pathological view generally taken of a mole—that it was a blighted or altered conception; the ovum having perished, its covering, or the placenta, if formed when this change took place, became attached to and continued to receive nourishment through the uterine walls and remained or became an organized product until it was thrown off; and this condition was attributed by some to the vitality retained in the villi of the chorion.

His experience had taught him to believe that if these cases did not receive treatment at a proper time there were two grave dangers to be apprehended—viz., hæmorrhage, which, if not an immediate cause of death, was capable of leading indirectly to that end, and septic poisoning. In the treatment, if the cervix was sufficiently dilated and hæmorrhage troublesome, the mass should be promptly removed. If this could not be done, a hot antiseptic vaginal douche should be given, followed by a careful and efficient tampon, with the internal administration of ergot and anodynes if required, directing quiet, rest, and a simple diet. In from twelve to sixteen hours the tampon should be removed and the foreign body extracted as completely as practicable; this would require a good, stout forceps. He had used the ordinary dressing forceps and placental forceps for the purpose. An excellent instrument in some cases was Emmet's curette forceps. The surface should be well curetted with a wire curette, the uterus thoroughly washed out with a hot solution of bichloride of mercury, and Squibb's crude carbolic acid or Churchill's tincture of iodine well applied to the surface. If much bleeding ensued—and this was not usual—the application of persulphate or perchloride of iron gave good results. The patient was put to bed and kept there as long as the indications in each special case might require; she was put upon a tonic treatment and the use of hot vaginal antiseptic washes. In from three to five days the uterus might need curetting again and another intra-uterine douche; then the application of iodine about twice a week, alternated occasionally perhaps with carbolic acid as long as might seem necessary, and the cure, if possible, completed of any uterine disease that might exist. The patient's general health was carefully looked after and her mind tranquillized.

A Review of the Treatment of Varicocele.—Dr. G. Frank Lydston, of Chicago, read a very elaborate paper on this subject. He said, in discussing the various merits of operative procedure, it was unnecessary to take them up in detail. The *raison d'être* of many specially devised and named operations was apparent only to the operator. For practical purposes the various methods might be divided into (1) acupressure, (2) subcutaneous deligation, (3) open deligation, (4) deligation with resection of veins, (5) deligation with resection of scrotum, (6) resection of the scrotum. The employment of acupressure, to the author's mind, was an evidence of a lack of faith in modern antisepsis. Gradual obliteration of veins had all the dangers of immediate deligation in a marked degree and had none of its advantages. The term acupressure covered practically all methods of gradual obliteration of the veins, of which Davat's operation was an illustration. Subcutaneous deligation was not essentially dangerous in skillful hands. Simple as the operation appeared, however, accidents had occurred. The operation was done in the dark and more tissue was included in the ligature than was necessary. Strangulation of tissue was not conducive to safety. Scrotal hæmatocele, phlebitis, septic infection, thrombosis, and embolism were possible. The vas deferens had been included in the ligature. He did not condemn the subcutaneous operation in suitable cases and in skillful hands, but he believed there were better and safer methods on the average. There was little choice between deligation without disturbance of the veins and deligation with resection of the veins, excepting the remotely greater danger of sepsis in the latter. Gould's method of division by cautery he believed to be the most dangerous operation yet devised. The dangers of the open method were in a less degree those of the subcutaneous deligation. If open deligation was determined upon, the operation should be done as high as possible in the straight portion of the veins and a single ligature applied to the vein. Deligation with resection of the scrotum he considered to be the ideal operation, in the majority of cases requiring surgical interference.

Silicate of Sodium; some New Methods of its Use in Surgery.—Dr. George A. Baxter, of Chattanooga, read a paper in which he said the jacket of baked silicate of sodium which he would present to the association possessed all the qualities to be found in the plaster jacket, firmness and support, and weighed actually one pound and six ounces. It was neater in appearance and finish, and could be perforated like leather for ventilation, which plaster could not. It was even lighter than leather without its costly process of construction, and had the same advantage over the woven wire jacket, with the additional advantage over both these latter and all others of this class, that it could be constructed by any surgeon at any time or in any place. The patient was suspended and a plaster jacket roughly placed around her and cut as soon as it had hardened enough to retain its shape, thereby lessening materially the time of suspension, the most trying ordeal with this or the plaster, and not without its dangers when long continued; the cut edges were bound together where it had been cut down directly in front with cords, and then a core of paper placed in the center. This paper core was used for two reasons: (1) to lighten the cast and take as little plaster as possible, and (2) to dry it the more readily by heating the inside. This done, the plaster was poured around the core and inside the cast, which gave him a mold of the body in extension and counter-extension, exact in every respect. Around this was made the silicate jacket after the manner of the plaster roller bandage, weaving half-inch metal strips in the meshes of the bandage at a distance of four inches apart around the whole cast, an inside lining of a knit shirt having been first placed over the cast. The whole was then placed over a coal-oil stove and allowed to dry out, which it did in from half an hour to two hours or less, especially if the cast had been previously dried. This process of heating not only dried the silicate, but baked it as well, rendered it impervious to the action of water or the perspiration, and gave it sufficient strength to allow of its being perforated for ventilation. It was then cut from the mold with a straight incision down the center, two pieces of leather, to which button-hooks or eyelets had been previously attached, were sewed up and down the front on each side, then the whole could be laced up solid or loosened and taken off at will. The necessity of taking off a jacket or leaving it on during the whole course of treatment would, of course, depend upon the character of the disease or the injury under treatment.

The Surgery of the Gall Bladder.—Dr. Edwin Ricketts, of Cincinnati, contributed a paper on this subject, in which he said that to Langenbuch was due the credit of totally extirpating the gall bladder, and to J. Marion Sims we owed a debt of gratitude for establishing the operation of cholecystotomy. He reported seven cases of gall stones.

Rectal Medication.—Dr. W. Hampton Caldwell, of Lexington, Ky., read a paper in which he said that several years ago he had been convinced of the utility and safety of rectal administration of medicine, and that he had ever since regarded it as a most important plan of treatment. Since we accepted the theory of the local origin or manifestation of the majority of diseases, this idea of rectal administration of medicines was more readily accepted as scientific in its applications than at any time heretofore. The rectal suppository, consisting of cacao butter, incorporated with the various therapeutical agents, afforded the most efficient and pleasant mode of administration in our possession. Rectal suppositories satisfied all requirements as a local or constitutional remedy. They were neat, convenient, and in almost every instance preferred by the patient to the administration of the same drug by the mouth.

Vaginal Cystotomy in a Child of Six Years.—Dr. Thad. A. Reamy, of Cincinnati, reported a case in which he had removed a stone weighing 365 grains, by vaginal cystotomy, from the bladder of a child six years of age, with injury of the ureter. Operations done for closing the bladder had been difficult, but ultimately successful. He exhibited the stone, and made some comments on the case.

The Surgical Treatment of Empyema.—Dr. James A. Goggana, of Alexandria City, Alabama, read a paper on this subject in which he said that during the last eighteen months he had treated six cases of empyema which had developed in the wake of pneumonia, all of which had gone on to perfect recovery. The patients had varied in age from three to thirty-five years. Surgical treatment was the one which had been the most successfully employed. Spontaneous cures, he said, were rare—so rare that surgical interference was the rule. There were many methods of operating for the removal of pus from the pleural cavity, but they might be classified under two general headings: 1. The closed method, which consisted in removing the pus by simple puncture with some kind of trocar or modern aspirator, and allowing the puncture to heal at once. 2. The open method, which consisted in making an incision more or less free with the introduction of some kind of drainage-tubes to maintain the perfect evacuation of the fluid, and admit of medicated washings, and to promote free ingress and egress of air that had been passed through an antiseptic dressing. The surgical treatment, then, being an absolute necessity, we could not overestimate the importance of making the diagnosis certain by resorting to exploratory puncture with a hypodermic syringe. We could assure the patient and friends that no evil results could come from this procedure, and that the prognosis positively depended upon this means of settling the diagnosis.

Officers for the Ensuing Year were elected as follows: President, Dr. L. S. McMurtry, of Louisville, Ky.; first vice-president, Dr. McF. Gaston, of Atlanta, Ga.; second vice-president, Dr. J. T. Wilson, of Sherman, Tex.; secretary, Dr. W. E. B. Davis, of Birmingham, Ala.; treasurer, Dr. Hardin P. Cochrane, of Birmingham, Ala. Place of meeting, Richmond, Va., on the second Tuesday in November, 1891.

Reports on the Progress of Medicine.

ANATOMY.

By MATTHIAS L. FOSTER, M.D.

The Fissure of Rolando.—Professor Cunningham (*Jour. of Anat. and Physiol.*, October, 1890) furnishes an account of the fissure of Rolando in man and the lower animals which is worthy of careful study. Regarding the time of its development in the human fœtus there is some variability. The more usual time is the last week or ten days of the fifth month, but it is not uncommon to meet with hemispheres well on in the sixth month of development with no sign of the fissure. As a general rule it appears to be developed in two separate and distinct portions. The lower portion always appears before the upper in the form of a shallow, oblique groove which represents the lower two thirds of the complete fissure. Its lower end is placed close to the coronal suture, perhaps subjacent to it, while the upper end lies farther back and reaches a point midway between the upper margin of the hemisphere and the Sylvian fossa. The upper portion of the fissure makes its appearance in the form of a deep pit or depression between the upper end of the lower portion and the margin of the hemisphere. It is separated from the lower portion by an eminence, over which a faint furrow is soon to be found running over its summit and partially uniting the two portions of the fissure. As development progresses the union becomes more complete and the intervening eminence is borne down into the bottom of the fissure. This union of the two portions takes place rapidly, as a rule, though in many cases the process is retarded. The intervening portion of the cortex is not obliterated; it disappears from the surface but can be found even in adult brains at the bottom of the fissure at the junction of its upper and middle thirds in the form of the deep annectant gyrus. In some rare cases the two original portions remain distinct throughout life. In these the intervening bridge of cortex remains on the surface.

This view is quite different from the one usually entertained, which pictures the fissure of Rolando as beginning as a slight furrow midway between the upper border of the hemisphere and the margin of the Sylvian fossa and extending gradually and continuously in an upward and downward direction. That this may be the course of development in certain cases the writer does not deny, but he maintains that there is no direct evidence to show that it is so. In one rather advanced hemisphere he found a clean-cut straight fissure with its extremities equally distant from the superior border of the hemisphere and from the fissure of Sylvius, of uniform depth, and at no point interrupted by an elevation of the bottom. This appearance leads him to believe that this fissure may have developed in the manner which is usually attributed to it.

From an analysis of fifty-two hemispheres, taken from children and adults, it was found that in sixty per cent. the upper end of the fissure cut the upper border of the hemisphere and appeared on the inner surface; in twenty-one per cent. it just reached the upper border, but did not show upon the inner surface, and in nineteen per cent. it fell short of the upper border. The upper end of the fissure does not overstep the upper border of the hemisphere until the beginning of the last month of intra-uterine development. In the eighth month it just reaches the margin.

From the seventh month onward the growth of the two bounding banks of the fissure does not proceed at an equal pace. There appears to be a greater growth energy in the posterior central convolution, and this leads to a partial overlapping of the ascending frontal convolution by the ascending parietal convolution. This is more obvious in the lower two thirds of the fissure, and it is owing to this that in the adult the fissure cuts into the cerebral surface in an oblique direction from before backward.

The position of the fissure of Rolando on the surface of the brain is subject to very slight alterations, and in all probability it becomes absolutely fixed at the third month of extra-uterine life, but its relations to the coronal suture are very different. The parietal bone and the area of brain immediately subjacent do not grow at an equal rate. In the early stages of its development the fissure of Rolando lies close to the coronal suture, because the parietal bone forms at a later stage a relatively greater extent of the cranial vault. The maximum amount of the district in front of the fissure of Rolando covered by the parietal bone is reached at the third month of extra-uterine life. From this stage on the coronal suture in its upper part falls back a little, and after a slight oscillation assumes at the fourth or fifth year of childhood a fixed position with reference to the fissure of Rolando. Its lower end is subject to very considerable variations regarding its relative position to the fissure which are not easy to understand.

In contradiction to Huschka, Rüdinger, and Passet, Professor Cunningham deduces from his observations that the lower end of the fissure of Rolando holds relatively the same place on the cerebral surface in the two sexes, and that at no period of growth does it exhibit in its position what might be safely regarded as sexual differences.

The Development of the Anterior Portion of the Human Brain from the End of the First to the Beginning of the Third Month.—According to an abstract in the *Fortschritte der Medicin* for November 1, 1890, Wilhelm His has obtained the following points from observations on the fœtal brain:

Like the spinal cord and medulla oblongata, the anterior half of the brain appears at first as a tube whose lateral walls are thicker than the dorsal or ventral. Each lateral wall is divided into dorsal and ventral halves, each of which ends anteriorly in front of the chiasma. During the course of development the ventral half inclines to bend inward, while the dorsal arches outward. The optic tract, of which a portion exists on the border of each division, behaves in a similar manner to the ascending roots of the nerves of sensation. From the ventral division the regio subthalamica of the mid-brain originates together with the regio mamillaris and the optic vesicle; therefore the retina is in correspondence with the anterior horns of the gray matter of the spinal cord and the motor ganglionic regions of the hind and mid brain. From the dorsal division the optic thalamus and the hemisphere, including the olfactory bulb and the corpus striatum, originate. After the formation of the optic vesicle the hemispheres develop from the dorsal, terminal portion of the fore-brain and are separated from each other by two fissures, one on either side of a crest which springs from the vertex of the skull. The fissure of Sylvius first appears during the fifth week as a shallow depression which corresponds internally to a convex swelling, the corpus striatum. A depression in the dorsal layer, the falciform fold, begins the separation of the lateral ventricles and the formation of the median walls of the hemispheres. The remainder of the undivided ventricle of the fore-brain occupies the space between the corpora striata.

The lateral wall of the third ventricle is divided into dorsal and ventral halves, which are best designated as the pars thalamica and the pars subthalamica, by a fissure which extends from the radicular fissure of the optic vesicle to the mid-brain, the sulcus of Monro. Longitudinal eminences grow inward from both parts. The roof of the third ventricle remains epithelial, and gives origin to the pineal gland, the tuberculum subpineale, and the pars habenularis. The floor of the third ventricle is divided into an anterior and a posterior portion, the latter including the mammillary and infundibular regions. The gradual development of the floor of the ventricle and of the pituitary gland is accomplished mechanically.

The olfactory lobe, which is separated from the lower portion of the hemisphere in the fifth week by a fissure which extends out from the fissure of Sylvius, divides into an anterior (trigonum, tractus, bulbus) and a posterior portion. In the interspace between the brain and the olfactory plate lie at first neither nerve fibers nor ganglion cells. In

the olfactory plate neuroblasts appear, which form the commencement of the olfactory ganglion, and this, later on, joins the brain and originates the olfactory nerve. Probably all of the ganglion cells which originate in the olfactory plate finally become connected with the covering of the trigonum. By the fifth week the walls of the brain have become here and there thickened or thinned, but each external depression corresponds to an internal protrusion, and each external fold to an internal sulcus. The increase in the thickness of the wall is mainly due to the increase in the white substance. Single formations, as the corpus striatum, stand out more prominently from their surroundings, while others disappear in the depth of the tissue. Structures which are originally separated become secondarily united, as the corpus striatum with the regio subthalamica and with the median plate which originates from the falciform fold.

Abnormal Arrangement of the Veins about the Popliteal Space.—Davidson describes the following abnormity (*Jour. of Anat. and Physiol.*, October, 1890): The popliteal vein occupied its normal position and relations in the space itself, but at the opening in the adductor magnus it gave off a very small branch which accompanied the femoral artery, while the main trunk of the vein passed up the back of the thigh, lying between the origins of the adductor magnus and the short head of the biceps. It reached the front of the thigh by piercing the adductores magnus and brevis immediately above the insertion of the adductor longus, and accompanied the femoral artery for the rest of the course. It was joined at the upper part of Scarpa's triangle by the small branch given off at the opening in the adductor magnus.

The short saphenous vein lay to the outer side of the middle line in the lower part of the popliteal space and soon pierced the fascia to lie on the posterior ligament of Winslow. It had no connection with the popliteal vein at this point, but continued vertically upward until it reached a point three inches above the condyle of the femur, where it pierced the origin of the short head of the biceps, ran for a short distance in the substance of that muscle, emerged, and joined the main trunk in the back of the thigh. The long saphenous vein was double, but occupied its usual position.

Absence of the Vagina.—Garde reports in the *Australasian Medical Gazette* a case in which the lower portion of the vagina was absent, leaving a vesico-rectal septum about three inches long. The other genital organs were present and active. Menstrual blood had accumulated in the upper part of the vagina about the cervix, forming a tumor about the size of an orange in the hypogastric region. An artificial vagina was made between the layers of the vesico-rectal septum on the lines laid down by Dupuytren and Amussat, and menstruation was afterward without pain.

Pseudo-hermaphroditism.—Winter describes the following case (*Zeitsch. f. Geburts. u. Gyn.; Am. Jour. of Obs.*, October, 1890): The patient, twenty-three years old, was of moderate size, rather large-boned, with large hands and feet, muscles moderately developed, subcutaneous adipose slight. The face was somewhat coarse-featured but distinctly feminine, and had no trace of beard. She was feminine in manner and had a broad, slightly projecting larynx, and well-developed breasts with retracted nipples. The pelvis was broad, the hips were well arched, and the symphysis pubis was more pointed than in the female. The abdomen was flat and not hairy. The external genitals resembled at first glance a perfect scrotum, with a small cleft opening below. The skin of the genitals was pigmented and corrugated, and the corrugations could be intensified by mechanical irritation. Testicles as large as pigeon's eggs were in the two halves of the scrotum; they moved upward on contraction of the abdominal muscles, but a cremasteric reflex was wanting; they could be pushed up to the inguinal openings but not through them; the left testicle was the more prominent and hung the lower. Both halves of the scrotum were connected by a distinctly feminine frenulum. At the posterior surface the epididymis could be felt closely applied, the enlarged part lying at the lower pole of the testicle, and continued above into the vas deferens, which could be followed to the inguinal ring with the other constituents of the cord. On holding the scrotal valves apart, it could be seen that the internal surface of the latter contained cutis, only the parts in the median line having a mucous-membrane character. The only trace of a penis was a moderately developed, imperforate clitoris, hardly projecting beyond the level of the surroundings; the two superior roots were folds of mucous membrane, the lower ones being more prominent from small caruncles. In the middle of this rhomb-shaped figure was a small opening, and a small sound introduced into this glided upward half a centimetre to the clitoris. More posteriorly the lateral borders of the unclosed part of the urethra came together as a small projection which was imperforate. Below this the folds again separated and surrounded the sinus urogenitalis, which was so wide that a finger could enter; if the side-wall of the latter was drawn upon, the opening into the closed urethra could be seen; the mucous membrane of this part of the sinus was smooth, that corresponding to the vagina more folded. The closed urethra was 7 ctm. long (the cleft portion remaining 2·5 ctm.), and wound around the symphysis with the usual curve. In the closed urethra two symmetrical openings could be seen several millimetres from the median line on the posterior wall, which could be penetrated by a sound about 1 ctm. backward and outward; these he considered to be the ejaculatory ducts. The surroundings of the sinus urogenitalis looked almost like a hymen at the posterior periphery. Under anæsthesia the vas deferens of either side could be distinctly traced from the inguinal ring; both ureters could be felt through the rectum; there was no trace of a prostate and no organ resembling the uterus.

A Sternopagous Monster.—Frazer (*Am. Jour. of Obs.*, August, 1890) reports the birth of a monster consisting of two male children united from the upper part of the sternum to the umbilicus. There were two heads, four perfectly developed arms and hands, four legs and feet, one thoracic cavity, two vertebral columns, and two sterno-costal walls, each wall formed by half the sternum and ribs of one fœtus and half of the other.

The Mucous Membrane of the Uterus.—Boldt (*Annals of Gyn. and Pæd.*, November, 1890) found, while studying the uterine mucous membrane during menstruation, that all the utricular glands were surrounded with rod and spindle forms, which could be traced from the base of the glands up to the surface. These forms were evidently rod and spindle shaped nuclei of smooth muscular fibers, the protoplasm of which was obscured by the treatment with Canada balsam. It appeared from this that, at the boundary between muscle and mucous membrane, the former sends out processes into the latter, so that the tubes forming the glands seemed to be surrounded by wide muscle processes, between which only moderately small portions of adenoid or lymphatic tissue remained visible. Between contiguous glands, relatively to their terminations in their *cul-de-sacs*, only muscular tissue and no lymphatic tissue could be discovered. The nearer the surface, the thinner were the glands accompanying the muscular processes.

In the cervix uteri of a virgin the mucous membrane is richly provided with adenoid or lymphatic tissue, and traversed by numerous small muscular bundles. The glands are tubular, irregular in outline, small in caliber, and covered with a single layer of columnar epithelium. Between the epithelium and the contiguous tissue no structureless membrane can be seen, but the boundary layer shows smooth muscular fibers in layers of varying width and sometimes wanting. In the latter case the boundary zone is formed of lymphatic tissue. The spindle formation of the individual muscle fiber can be demonstrated, but the rod formation of the nuclei may not be apparent. Sometimes in the muscular layer there are formations which resemble lymph corpuscles, which are surrounded by branching processes.

In a multipara the cervical mucous membrane has a basis of fibrillary connective tissue, interspersed with a small quantity of lymphatic tissue. Many of the connective-tissue bundles are extensively infiltrated with a ground substance of cullagen, which makes them strongly refractive of light. The gland ducts are wider and more branching than in the virgin. The boundary layer between the epithelium and the surrounding tissue consists of a structureless membrane and a delicate fibrillary connective tissue, whose irregular elevations are covered with columnar epithelium. Between the basal and the boundary layers there is a layer of smooth muscular fibers. Each gland has an accompanying layer, sometimes wanting, of muscular fiber, composed of two or more muscle spindles. Occasionally a section of the gland is found with no muscle layer in its surroundings. The muscle layer which accompanies the glands is not continuous, but is pierced in many places, and surrounds the glands in a kind of woven formation.

The mucous membrane from the fundus of a virgin uterus is composed of moderately wide muscle bundles within the adenoid or lymphatic tissue, which are often combined with muscular processes which appear to be woven around the tube-like glands. These webs are never very wide, and are composed of only two or three muscle spindles. Muscle fibers may be absent, and then the boundary zone is made up of adenoid tissue, while a structureless membrane is rarely definable.

The utricular glands from the corpus uteri of a multipara show the attendant web of muscular tissue much more clearly defined than the same structure in a virgin uterus.

As the result of his studies, Boldt concludes that not only is the adenoid or lymphatic tissue interwoven with muscular tissue, but the utricular glands of the cervix and of the body of the uterus are associated with a layer of smooth muscular fibers arranged in a web-like manner. These muscular processes have a relation to the muscle bundles, the uterine wall, as well as to those which are associated with the lymphatic tissue of the mucosa. These gland muscles are developed most at the border zone, between mucous membrane and muscularis, and become less pronounced near the surface of the mucous membrane, but accompany the glands as far as their openings into the uterine cavity.

The Utero-placental Blood-vessels.—Bumm (*Arch. f. Gyn.; Fortschritte der Medicin*, Oct. 1, 1890) describes the utero-placental vessels as follows: The veins are the more easily seen. They lie mainly upon the cotyledons, seldom on their borders, and never in their septa. In the superficial layers of the serotina they appear as tortuous, thin-walled sinuses, 0·5 to 1 mm. in diameter in the fresh state, and always are filled with blood. The upper part of their walls has sometimes remained attached, and then they resembled canals on the serotinal covering of the placenta. Injection of colored gelatin makes them more distinct. The nuclei of the endothelial cells which form the inner layer are rather distant from one another. The endothelial layer ends at the opening of the vein into the placental spaces. External to this layer is a layer of filiform connective tissue with spindle cells. After several turns it turns crosswise against the final layer of the serotina to open into the placental spaces. The tips of villi are always found at the borders of the venous openings, and the blood in the spaces is continually connected with the veins by means of the villous tips.

The arteries usually lie in the septa between the cotyledons, less often with the veins. They are more convoluted and tortuous than the veins and usually do not divide. They are lined by endothelium resembling that of the veins, outside of which is a layer of fibrous connective tissue with round and sometimes rod-shaped nuclei, thicker and more compact than in the veins. Outside of this is the large-celled decidual tissue. The arteries penetrate the decidua and after a very tortuous course open into the placental spaces either at right angles or parallel to the decidual surface. The mouth of the artery is sometimes narrowed and causes a spur-like projection. There are no villous tips to be found here as at the mouths of the veins.

The nutrient vessels are much finer, are not convoluted, give off branches, and terminate in a capillary system.

From these observations Bumm concludes that the placental spaces take the place of a capillary system, that each cotyledon forms a distinct circulatory field for the maternal blood, the current passing from the mouth of the artery at its border to the opening of the veins at its surface. Lower down near the chorion is the only place where the cotyledons cling together. The circulation is the most active in the upper part of the cotyledons and that nearest the decidua.

Tubal Pregnancy.—Abel (*Ctrlbl. f. Gyn.; Am. Jour. of the Med. Sci.*, November, 1890) maintains that in the beginning a decidual membrane is formed from the endometrium, and that Friedländer's cellular layer is not fully developed in this. The superficial layer of the uterine decidua is present in a degenerate form at the second month. The tube external to the fœtus usually is not changed. In the fœtal sac the mucous membrane of the tube forms a decidua vera which is best developed at the extremity of the ovum until the serotina has become completely atrophied. Beneath the serotina, epithelium from the mucous membrane of the tube is often found. The epithelium of the villi of the chorion is threefold—two layers over the fœtal and one over the maternal vessels. The spaces between the villi are dilated maternal vessels whose walls are not broken through by the villi of the chorion.

The Origin of the Amniotic Fluid.—Nagel (*Arch. f. Gyn.; Am. Jour. of Obs.*, November, 1890) suggests that the Wolffian bodies may be the source of the amniotic fluid. He bases this suggestion upon the fact that during their entire existence as independent organs they present the anatomical characteristics of secreting organs in full activity, justifying us in considering them as important elements in embryonal nutrition. He discusses their anatomy at some length and concludes that at the beginning the permanent kidneys greatly resemble the Wolffian bodies and are capable of functionating in the second month of gestation. The Wolffian bodies are, he contends, capable of performing their functions at an earlier stage, and the amniotic fluid is in part a product of embryonal metabolism even in the beginning of pregnancy. Beginning with the subinvolution of the Wolffian bodies, the kidneys gradually assume the functions of the former, and for a time the provisional and the permanent organs act in concert, so that the renal activity is not suddenly assumed by the kidney. Before the sphincter vesicæ is so far developed as to permit the existence of a urinary bladder, the secreted urine flows directly into the amniotic fluid.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.
